Background Paper

On the

NTI Uranium Policy

Department of Lands and Resources
Nunavut Tunngavik Incorporated
November 2006

Preface

NTI has prepared a *Policy Concerning Uranium Mining in Nunavut*—the *Uranium Policy*. This paper is intended to provide the reader of the *Uranium Policy* with additional background information beyond that presented in the policy document. The topics briefly cover many aspects of uranium mining and the nuclear industry in general. Although the topics are organized in the same order as topics are presented in the *Uranium Policy*, there is not an exact link between the headings in the two documents.

Table of Contents

Preface ii
Table of Contents iii

1 Introduction to the Uranium Policy 1
1.1 Lands and Minerals in Nunavut 1
1.2 NTI's Mining Policy Framework 2
1.3 Developing the Uranium Policy 4
1.4 Policy Considerations 5
1.5 Scope of the Policy 6

2 Uranium and Radioactivity 8
2.1 Uranium and Thorium 8
2.2 Radioactivity and Radiation 8

3 Nuclear Power 10
3.1 Background on Nuclear Power 10
3.1.1 The Need for Electricity 10
3.1.2 Using Nuclear Energy to Produce Electricity 11
3.1.3 Concerns about Nuclear Power 11
3.2 Future for Nuclear Power and Uranium 14
3.2.1 Outlook for Nuclear Power 14
3.2.2 Outlook for Uranium 14
3.3 Nuclear Power and Climate Change 15
3.4 Disposal of Nuclear Waste on IOL 17
3.5 Use of Uranium for Peaceful Purposes Only 17
3.6 Summary 19

4 Uranium Exploration and Mining 20
4.1 History of Uranium Mining in Canada 20
4.1.1 The Early Years 20
4.1.2 The Modern Era 20
4.2 Uranium in Nunavut 21
4.2.1 Overview 21
4.2.2 The Kiggavik-Sissons Project 22
4.3 Uranium Exploration, Mining and Milling 23
4.4 Saskatchewan as a Model for Uranium Mining 24
4.5 Benefits from Uranium Exploration and Mining 26
4.6 Uranium Potential on Inuit Owned Lands 28
4.7 Impacts of Uranium Exploration and Mining 28
4.7.1 Protection of Human Health 29
4.7.2 Regulatory Requirements 30
4.7.3 Wildlife 32
4.7.4 Management of Tailings and Waste Rock 33

4.8 Community Participation 34

5 Acronyms and Initialisms 35

Appendix 1 Exploration, Mining and Milling of Uranium 36
1.1 Introduction 36
1.2 Exploration 36
1.3 Mining 38
1.4 Milling of Uranium Ore 40
1.5 Radioactivity in Mining and Milling Wastes 42
1.6 Management of Waste Rock 43
1.7 Management of Tailings 43
1.8 Reclamation and Decommissioning 45
1.9 Monitoring 46
1.10 McClean Lake Operation 47

1 Introduction to the Uranium Policy

Nunavut has excellent potential to host economic uranium deposits and, with the recent increase in the price of uranium, considerable exploration activity for uranium and the acquisition of mineral rights is taking place. This represents both an opportunity and—for some people—a source of concern. Some of these concerns were expressed during the review of the 1989 proposal to mine the Kiggavik-Sissons uranium deposit west of Baker Lake. The purpose of the Uranium Policy is to clearly establish and set out NTI's position on uranium mining in Nunavut, with particular emphasis on IOL.

1.1 Lands and Minerals in Nunavut

Under the Nunavut Land Claims Agreement (NLCA), Inuit—through the Regional Inuit Associations (RIAs)—hold title to 356,000 square kilometres of land, called Inuit Owned Lands, or IOL. The IOL on which the Crown owns the minerals (about 98% of Nunavut and 90% of IOL) is referred to as "Surface IOL". The RIAs administer these lands and provide access through the issuance of Land Use Licences and Commercial Leases. The IOL for which NTI holds title to the minerals—the remaining 38,000 square kilometres, or 2% of Nunavut—is referred to as "Subsurface IOL". NTI administers mineral rights on Subsurface IOL (except for rights grandfathered under the CMR) through the issuance of Exploration Agreements, under which the holder has the right to obtain a Production Lease for the purposes of mining if certain conditions are met.

An internal NTI/RIA document called The Rules and Procedures for the Management of Inuit Owned Lands (the Rules and Procedures) establish a comprehensive set of directions to guide the land administrations in the management of IOL. The Rules and Procedures do not have any restrictions pertaining strictly to uranium and thorium, either with respect to surface rights or to subsurface rights.

The federal Department of Indian Affairs and Northern Development (INAC) administers the rights to minerals on all Crown land and all Surface IOL through the Canada Mining Regulations (CMR). It also administers rights to those areas of Subsurface IOL for which there were mineral rights under the CMR when the NLCA came into effect. Mineral rights granted or administered under the CMR do not restrict or prohibit the exploration for or mining of uranium.

Some parcels of IOL have potential for the discovery of uranium deposits and at least one (BL-22) has known deposits. Among the reasons that Inuit selected such parcels were the opportunities to obtain the benefits of future uranium mining and to participate in decisions related to the management of this mining. However, under its Exploration Agreements, NTI currently excludes the right to explore for and mine uranium and thorium.

The RIAs issue access rights for the purpose of exploration and mining –including for uranium—to a party that holds mineral rights granted under the CMR. If the holder of the mineral rights is unable to obtain the consent of the RIA, the NLCA provides that the holder may apply to the Nunavut Surface Rights Tribunal for an entry order for its required purpose.

1.2 NTI's Mining Policy Framework

The NLCA and directives such as NTI's by-laws and the Board's *Results Policies* establish the overall direction for NTI. The *Mining Policy* and other policies and resolutions that relate to lands and resources provide a finer level of detail with respect to specific matters. The Rules and Procedures provide operational details for the management of lands and minerals consistent with the policy directives. Taken together, these provide a framework in which the matter of uranium mining must be considered.

It is useful to briefly examine NTI's existing policies regarding mining and how they relate to the *Uranium Policy*. NTI presently has two policies that are relevant to mining—the *Mining Policy*, and the *Water Policy*. NTI and the RIAs are also developing A *Reclamation Policy*[1], which will be completed soon. The *Mining Policy* has as its subject the "development of mineral resources in Nunavut". As such, it deals in a general way with all aspects of mining and presents NTI's position on mining on all lands in Nunavut. It states that "NTI will support and promote the development of mineral resources in Nunavut if there are significant long-term social and economic benefits for the Inuit of Nunavut, and it is consistent with protecting the eco-systemic integrity of the Nunavut Settlement Area".

The *Water Policy* deals primarily with Inuit rights relating to water use on IOL and establishes guidelines for the use of this water. The *Reclamation Policy* will address the reclamation of IOL following a land use operation, including the reclamation of a minesite. Although none of the policies makes a specific reference to uranium exploration and mining, all have statements about mining or land use activities in general that would be applicable to uranium exploration and mining activity.

In addition to these policies—which can be considered the comprehensive treatment of an issue supported by background information and reflecting a series of discussions and/or consultations—NTI may also state a position on an issue by means of a simple resolution of the Board. In some cases, these can be considered to be an interim position pending a more detailed treatment of a topic. NTI has passed two resolutions that relate to uranium mining.

A 1997 resolution indicated opposition to Greenland's consideration of plans to store nuclear waste and other nuclear material from Russia and the USA. The resolution opposed any plans for the storage of nuclear goods or the transportation of such goods in

[1] At this time, the Reclamation Policy has not yet been approved by the Board of Directors.

the Arctic. In 1999, NTI passed a resolution that recognized the economic, social and environmental issues around uranium mining and directed the Department of Lands and Resources to develop a discussion paper concerning uranium mining in Nunavut and for the NTI Executive Members to authorize a committee to create a draft policy concerning uranium mining for presentation to the NTI Board. The resolution lists various aspects of uranium mining and nuclear energy that should be considered in the policy.

It is important to note that none of NTI's by-laws, policies, resolutions, or Rules and Procedures restrict or prohibit uranium exploration and mining on IOL.

NTI does not just represent Inuit on Nunavut issues, but participates in international groups with respect to broader pan-Arctic issues. The Inuit Circumpolar Conference (ICC) is one such organization. At this time, the only specific policy direction that relates to uranium mining in Nunavut is that expressed by two resolutions of the ICC, of which NTI is one of the Canadian representatives.

The first of these, in 1983, indicated the opposition of the ICC to the testing of nuclear weapons and the use of nuclear reactors in the Arctic, as well as to the "exploration and exploitation of uranium, thorium, lithium or other materials related to the nuclear industry". It appears that the 1983 ICC policy was intended to deal mainly with nuclear weapons and is now in need of clarification and updating. Among the ICC members, only Greenland has actually instituted a prohibition on uranium mining. None of the government jurisdictions representing the four Inuit regions in Canada has such a prohibition and the Kivalliq is the only region of Nunavut that is currently subject to uranium-specific requirements established by a land use plan.

A later ICC resolution in 1998 recognized that uranium exploration is already taking place and that significant deposits exist. This resolution limits the concerns about uranium mining to the "potential environmental and social impacts" of uranium mining and appears to suggest that "new technology in mining" may allow mining to be done in such a way as to minimize the concerns and allow Inuit to realize the "potential economic steps forward for Inuit." It appears that the intent of the resolution is to encourage further research on uranium mining so that the environmental and social concerns may be addressed. The policy thus may be seen as opening the door to uranium mining, following a favourable review by the ICC.

In the Implementation section, the *Uranium Policy* states that NTI will encourage the ICC to review, clarify and update its position on uranium mining.

1.3 Developing the Uranium Policy

Need for a Uranium Policy

If NTI has its *Mining Policy* and other policies, one might ask why it needs a separate policy on uranium. The answer is that the *Uranium Policy* addresses specific issues, as follows:

1. The radioactive nature of uranium and associated elements (e.g. radon and radium) require that special measures be followed in order that the health of the workers and the general population is not harmed and no damage is done to the environment.

2. The possible uses of the product of uranium mining—that is, uranium—are a matter of concern to some people and require consideration.

3. The negative public reaction to the 1989 proposal to mine the Kiggavik deposits west of Baker Lake requires that issues related to uranium mining be examined.

4. Uranium exploration is taking place in several areas of Nunavut, including on IOL, and NTI does not have a clear and consistent position on this activity.

5. There are no provisions in the Rules and Procedures that refer specifically to uranium and there are no terms and conditions in the licences and leases that grant surface access to IOL.

Development of the Policy

Preliminary work on the development of an NTI policy on uranium mining was done in the period between 1996 and 1999. In June, 1999, the NTI Board passed a resolution that the NTI Lands Department begin the development of a discussion paper on issues that are relevant to the creation of a comprehensive *Draft Policy Concerning Uranium Mining in Nunavut* (the Uranium Policy). The Board resolution also provided for the formation of a committee to develop the draft policy, which is then to be presented to the Board for its consideration. Some work on the discussion paper was done over the next five years, but it was not until the late summer of 2004 when, due to increased uranium exploration activity in the Kivalliq and Kitikmeot regions, work on the discussion paper was taken up in earnest. A draft discussion paper with proposed policy elements was completed in March 2005 and presented to NTI and RIA staff and executive members for review.

Discussion and consultation among NTI and RIA staff and members resulted in the development of a Draft Consultation Document and Draft Uranium Policy, prepared by the Lands and Resources Department and presented to the Land Policy Advisory Committee (LPAC) members in March 2006. These documents were then distributed to several Nunavut organizations for their review. Comments and suggestions for

improvement from this process were incorporated into the second draft of the policy document and into the Consultation Document, which became this paper.

1.4 Policy Considerations

In trying to establish a general position on uranium mining, NTI was required to choose between two options as follows:

1. NTI would continue to exclude the rights to explore for and mine uranium on subsurface IOL in the agreements it makes with companies. To be consistent, NTI would also attempt to restrict or prohibit uranium exploration and mining on Surface IOL and possibly even on Crown land.

2. NTI would remove the restrictions that apply to Subsurface IOL and would not oppose uranium mining on IOL or Crown lands. In order to ensure that exploration and mining are done in a way that will provide the greatest possible benefit to Inuit with the least possible negative impact, NTI would recommend or require that certain measures be taken.

If NTI believed that uranium mining could not be carried out in a way that would protect the health of the mine workers and residents of nearby communities as well as the environment, it would be inclined to choose the first option. Concerns about the use of nuclear power or the possibility that Nunavut uranium would end up in nuclear weapons might also result in this choice. Many people still have concerns about nuclear reactors and the proliferation of nuclear weapons, although as discussed in this paper, much has been done to deal with these concerns. With respect to the issues related to the actual exploration and mining operations, NTI has seen that the mining industry is highly regulated and can be carried out in a way that protects people and the environment. The result of this is that many of the concerns expressed by opponents of the Kiggavik-Sissons project with respect to the environmental assessment process, regulatory matters, and issues related to impacts and benefits of exploration and mining operations have been substantially addressed or can be addressed as set out in the Uranium Policy.

An approach based on the first option would present NTI with several other difficulties:

1. Uranium is a common element that occurs in many types of rocks and minerals. Thus, at least small amounts of uranium would likely be mined in any mining operation for other commodities. An attempt to restrict the mining of uranium, but not other substances, raises the question as to what amount of uranium would be allowed in the mining of those substances. An arbitrary limit as to what is a uranium mine and what is not would need to be established.

2. NTI holds the mineral title only to Subsurface IOL, which makes up less than 2% of the land in Nunavut. While Inuit (through the RIAs) are the owners of Surface IOL, the Crown owns the minerals, which includes uranium. Mineral rights

granted under the CMR include the right to explore for and mine uranium. Thus, NTI would be able to enforce its prohibition only on 2% of Nunavut, while exploration and mining would be allowed on the remaining 98%, subject to the regulatory requirements.

3. An attempt to put an arbitrary prohibition on uranium mining on Subsurface IOL would undercut the environmental and socio-economic assessment process—a key element of the resource management regime in Nunavut—in assessing the potential impacts and benefits of a mining project proposal. It would eliminate the possibility of a proponent demonstrating that it could mine uranium with minimal impacts while producing important benefits. An NTI prohibition could also be at odds with a land use plan or with the sentiment expressed by the people of a community or region who may well decide that they want a uranium mining project to proceed.

4. In the land selection process for the NLCA, Inuit selected some parcels of land with identified deposits of uranium or with potential for the discovery of uranium deposits. Inuit would not realize the potential of these parcels through royalties and socio-economic benefits, if uranium mining were not allowed.

In addition to the above reasons why it would be difficult or unattractive for NTI to oppose uranium mining, the following are reasons why NTI would choose the second option:

1. The use of nuclear energy to produce electricity— "nuclear power" —can play an important role in the mix of solutions to reduce the global emission of greenhouse gases and help avoid climate change.

2. Uranium mined in Nunavut may make a contribution to nuclear power and the reduction of greenhouse gases.

3. Nunavut has excellent potential for uranium deposits. The exploration for and mining of these deposits has the potential to bring significant economic benefits to Inuit.

4. Uranium mining can be carried out in a way that minimizes the potential impacts on people and the environment.

5. Other needs and concerns with respect to uranium mining can be addressed as set out in this policy.

1.5 Scope of the Policy

The Uranium Policy is primarily concerned with NTI's position on uranium exploration and mining in Nunavut, with particular emphasis on Inuit Owned Lands. Thus it deals

with the potential benefits and impacts of these activities and the participation of local people in the activities and in decision-making. However, because the main use of uranium is as a source of energy—for both peaceful and military purposes—the NTI Board has required that the policy also address the question of the end use of any uranium produced in Nunavut. For this reason, the policy deals with the use of uranium as a fuel for nuclear reactors that provide a significant part of the electricity used around the globe. The Policy also deals with measures that are taken to ensure that this uranium is not diverted for use in nuclear weapons. Thus the policy expresses NTI's support for the responsible and peaceful uses of nuclear energy and describes NTI's position on the way in which uranium mining should be carried out. It does not deal with the possible use of nuclear reactors in Nunavut. Nor does it deal with the possible disposal of nuclear fuel waste in Nunavut, an option that has already been decided against by the NTI Board.

Although the mining of thorium in Nunavut is not being considered—and may never be—some NTI and ICC statements include a reference to thorium along with uranium. In the policy context, unless the meaning indicates otherwise, reference to "uranium" can be understood to include "thorium". (Thorium is briefly described in the following section.)

2 Uranium and Radioactivity

2.1 Uranium and Thorium

Uranium is a metal and one of the heaviest elements. Its most distinctive physical property is its radioactivity, which contributes largely to the natural background radiation of the earth. Uranium is one of the most abundant elements found in the earth's crust. It can be found almost everywhere in soil, rocks, rivers, and oceans. Traces of uranium are even found in food and human tissue. Uranium is more abundant than gold and silver and has about the same abundance as lead. It can take many chemical forms, but in nature it is most commonly found as an oxide (that is, in combination with oxygen)—U_3O_8.

Concentrations of uranium vary according to the substances with which it is mixed and according to the places where it is found. For example, when uranium is found in granite, a very common rock, there are approximately four parts of uranium per million parts of granite, i.e. 4 ppm. Concentrations of uranium that are economic to mine are considered ore. The most common ore mineral is uraninite, sometimes in the form known as pitchblende. In a low-grade orebody (e.g. 0.1% uranium) the concentration is 1,000 ppm uranium and in a very high-grade orebody (e.g. 20% uranium) the concentration is 200,000 ppm uranium. Uranium deposits are found all over the world, but the only high-grade deposits being mined are located in Canada.

Naturally occurring uranium is made up primarily of two different types of uranium atoms, or isotopes. Approximately 99.3% is uranium 238 (U-238), and 0.7% is uranium 235 (U-235). Under certain conditions the nucleus of U-235 can be made to split, or fission, in a nuclear reactor, producing large amounts of energy in the process. Because of this property, U-235 plays an important role in the generation of nuclear power.

Because some existing policy statements mention thorium, it is useful to briefly describe it. Thorium is a naturally occurring, slightly radioactive metal. It is found in small amounts in most rocks and soils, where it is about three times more abundant than uranium and there are substantial deposits in several countries. It has many industrial applications, either as a pure metal or in its oxide form, and like uranium, can be used as fuel in a nuclear reactor. Much development work is still required before the thorium fuel cycle can be commercialized. India has particularly large reserves of thorium and has planned its nuclear power program to eventually use it exclusively, phasing out uranium. There is currently no thorium production in Canada, nor, to our knowledge, is any planned.

2.2 Radioactivity and Radiation

We are all familiar with some forms of radiation, such as visible light, microwaves, or radio waves. These are known as non-ionizing radiation. In this paper, we are concerned

with ionizing radiation, which has the potential to cause damage in living tissue—we will refer to this simply as "radiation". The earth and all living things on it are constantly bombarded by radiation from space, similar to a steady drizzle of rain. This cosmic radiation varies in different parts of the world due to differences in elevation and the effects of the earth's magnetic field.

All matter is composed of atoms and many atoms are unstable; that is, they are in a constant process of rearranging themselves. When the nucleus of an atom attempts to become more stable, it releases energy—known as radiation. Once this happens the original atom changes into a new atom. The spontaneous change in the nucleus of an unstable atom that results in the emission of radiation is called radioactivity; this process of change is also often referred to as the "decay" of atoms. The types of radiation associated with radioactivity are alpha particles, beta particles and gamma rays. (These types of radiation, as well as the release of neutron particles, are also produced by fission in a nuclear reactor.)

Radioactive material is found throughout nature and continuously releases radiation. This "background radiation" occurs naturally in the soil, water, and vegetation. Low levels of uranium, thorium, and their decay products are found everywhere. Some of these materials are ingested by people with food and water, while others, such as radon, are inhaled. The dose from earth-based sources varies in different parts of the world. All of these kinds of radiation are, at low levels, naturally part of our environment. We are also frequently exposed to low levels of man-made radiation in X-rays—such as, dental and chest X-rays—and from consumer products, such as tobacco (polonium-210), building materials and combustible fuels (gas, coal, etc.).

While exposure to background radiation and the man-made sources described in the preceding paragraph do not appear to be harmful at low doses, exposure to more intense levels of radiation can cause cancer and birth defects and at high levels can cause radiation poisoning and death. Fortunately, such exposure to moderate to high doses of radiation rarely occurs due to the safety precautions employed at nuclear facilities and the strict regulation of all aspects of the nuclear energy industry and all uses of nuclear substances.

Public health studies do not indicate an increased occurrence of cancer for low radiation doses below 100 millisievert (mSv). However, the conservative approach is to assume that any amount of radiation may pose some risk. The 2005 report of the Chernobyl Forum (p. 12) states that while the annual natural background doses of humans worldwide average 2.4 mSv, the typical range is 1 – 10 mSv. The report notes that lifetime doses due to natural radiation would thus be about 100 – 700 mSv. The Canadian Nuclear Safety Commission (CNSC) limit for nuclear energy workers is a maximum of 50 millisieverts (mSv) per year or 100 mSv over five years.

3 Nuclear Power

3.1 Background on Nuclear Power

3.1.1 The Need for Electricity

As of 2004, the generation of electricity made up 16.2% of the world total final energy consumption. The electricity comes from the following sources: 39.8% from coal, 16.1% from hydro, 15.7% from nuclear, 19.6% from natural gas, 6.7% from oil and 2.1% from other sources. [2]

It is estimated that by 2050, the earth's population will increase by 50% from 2000 levels to around 9 billion people. Over 90% of world population growth in the foreseeable future will be in the less developed countries. The increase in global population coupled with the desire of people in less developed countries to improve their standard of living will result in a significant increase in total energy consumption, including electricity. During this 50-year period, it is estimated that humanity will require more energy than the total used in all previous history. At the same time, there are increasing concerns about the environmental impact of energy use and indications that not even the present use is environmentally sustainable.

Much of the required energy will continue to come from coal, oil and natural gas, which are referred to as "fossil fuels" because they are derived from plants and animals that lived millions of years ago. However, many experts estimate that global production of oil has either peaked or is about to and it is likely that shortages will continue to keep prices high. Although global production of natural gas is not predicted to peak for several decades, prices have already increased substantially in recent years and remaining resources of oil and gas may become too valuable for other purposes—such as for transport and for use in the petrochemical industry—to be used for generating electricity. In addition to the looming shortages of oil and gas, the burning of these substances to produce electricity has many drawbacks. Although, the world still has huge supplies of coal, a way must be found to greatly reduce the greenhouse gas emissions and pollution that result from its use. The capture and storage of the emissions is being proposed as a solution, but this will require a commitment to incur the vast expenditures required to perfect the technology and to install the facilities. For these reasons, it is likely that nuclear power will continue to play an important role in the global production of electricity.

It is important to stress that no one is currently proposing that nuclear power be used in Nunavut. This background section on nuclear power is presented so that readers will have a better idea of how uranium mined in Nunavut would be used in other parts of Canada and in other countries to produce electricity.

[2] Key World Energy Statistics 2006; International Energy Agency.

3.1.2 Using Nuclear Energy to Produce Electricity

Electricity is produced in nuclear reactors[3] through the process of nuclear fission (section 2.1). This reaction releases a large amount of heat, which is used to generate steam, which turns turbines, thereby generating electricity. We refer to this electricity as nuclear power.

The term "nuclear fuel cycle" is used to describe the whole cycle by which uranium is used to produce electricity. It is comprised of the initial stages involving exploration, mining, and milling; the intermediate stages of refining, conversion and fuel fabrication; and the final stages involving electricity generation at a nuclear reactor and storage and disposal of the nuclear fuel waste. The *Uranium Policy* focuses on the initial stages of the cycle involving exploration for uranium deposits and the mining and milling of the ore in Nunavut.

Currently in Canada, all mining of uranium is done in Saskatchewan, the intermediate stages are done in several plants in Ontario, and electricity generation is carried out in nuclear reactors in Ontario, Quebec and New Brunswick. Nuclear reactors are always located in areas which have a large population and high energy requirements, such as southern Ontario, which gets about half its electricity from nuclear reactors.

Although some of the uranium fuel used in the reactors comes from the recycling of other nuclear materials, about 60% of it currently comes from mined uranium. Canada and Australia are the world's biggest suppliers of mined uranium, with several other countries making significant contributions. Canada is the world's leading producer of mined uranium, all of it from Saskatchewan mines. This production accounted for 28% of world production in 2005, a share that will increase significantly when the Cigar Lake mine comes into production in about 2009.

The uranium and nuclear industries are very important to the Canadian economy and stand to benefit from the increased global demand for electricity. With 18 operating nuclear reactors[4] and more planned for Ontario, Canada is also a major consumer of uranium.

3.1.3 Concerns about Nuclear Power

Concerns about nuclear energy typically include the safety of the reactors, the economics of producing electricity, the disposal of nuclear waste, and the possible diversion of uranium for use in building nuclear weapons. We will examine each of these briefly.

[3] Although there are many kinds of reactors, our discussion is based on the CANDU reactors used in Canada and a few other countries.

[4] Ontario also has two reactors at the Pickering A station that are out of service and two at the Bruce A station that are under refurbishment and expected to be online in 2009 and 2010.

Safety

Radioactivity and radiation are a serious concern to many people and lie at the root of the opposition to nuclear energy. This is in part because of the fact that although the risk of a serious accident is very low, the consequences of such an accident may be enormous. Thus although the nuclear industry has an excellent safety record in Canada and worldwide compared to the other energy industries—there being only two significant accidents in more than 10,000 reactor-years of commercial operation of nuclear power reactors in 32 countries—it is those two accidents that many people think of when the question of nuclear safety is discussed.

The accident at the Chernobyl nuclear power plant in 1986 was the most severe in the history of the nuclear power industry, causing a huge release of radionuclides over large areas of Europe. The accident was the product of a flawed Soviet reactor design, minimal operator training, and a series of flagrant deliberate violations of safe operating procedures. It was the only accident in the history of commercial nuclear power where radiation-related fatalities occurred. In 2005, several United Nations agencies and representatives of Belarus, Ukraine and the Russian Federation, the three countries most affected, participated in a review of the disaster and its health, environmental and socio-economic consequences. The following comments are taken from a report produced by the Chernobyl Forum[5].

Emergency workers and onsite personnel, about 1000 people, received the highest radiation doses and some (at least 28) of them died as a result. In addition, projections by an international expert group projected that, "among the most exposed populations, total cancer mortality might increase by up to a few per cent owing to Chernobyl related radiation exposure." A high incidence of childhood thyroid cancer caused by radioactive iodine fallout was one of the main health impacts of the accident, accounting for around 4000 thyroid cancer cases by 2002.

An area of approximately 200,000 square kilometres in Europe was contaminated with radiocaesium and over 335,000 persons had to be relocated. The report notes that since 1986, "radiation levels in the affected environments have declined several hundred fold because of natural processes and countermeasures. Therefore, the majority of the 'contaminated' territories are now safe for settlement and economic activity. However, in the Chernobyl Exclusion Zone and in certain limited areas some restrictions on land-use will need to be retained for decades to come."

According to a report by IAEA, the Chernobyl accident "can be said to have flowed from deficient safety culture, not only at the Chernobyl plant, but throughout the Soviet design, operating and regulatory organizations for nuclear power that existed at the time."[6] A

[5] The Chernobyl Forum: 2003-2005: Chernobyl's Legacy: Health, Environmental and Socio-economic Impacts and Recommendations to the Governments of Belarus, the Russian Federation and Ukraine; second revised edition; 2005. (see www.iaea.org).

[6] IAEA's International Nuclear Safety Advisory Group (INSAG), The Chernobyl Accident: Updating of INSAG-1 (INSAG-7, 1992, p.24).

recent analysis[7] says that "the safety of all Soviet-designed reactors has improved vastly. This is due largely to the development of a culture of safety encouraged by increased collaboration between East and West, and substantial investment in improving the reactors." Perhaps this is the major positive outcome of the accident.

The Three Mile Island accident happened in a nuclear reactor near Harrisburg, Pennsylvania. It was due to a combination of equipment failure, inadequately designed instrumentation, and the inability of plant operators to understand the reactor's condition. In contrast to the Chernobyl accident, there were no injuries, deaths or discernable direct health or environmental effects as a result of the Three Mile Island accident.

Economics

With respect to the economics of nuclear power, although the initial costs of building nuclear reactors is high compared to that for other methods of electricity generation, the operating costs tend to be much lower. The overall cost of producing nuclear energy is comparable to or lower than the cost of producing electricity by other means, especially if all the costs of the environmental impacts of the energy sources—including a cost for the emission of greenhouse gases—are considered. Furthermore, new reactor designs incorporate new safety features to ensure that accidents do not happen as well as significantly lower construction and operating costs compared to current operating models.

Nuclear Fuel Waste Disposal and Nuclear Proliferation

The disposal of the waste from a nuclear reactor is considered by some people to be the major drawback of the use of nuclear power. This issue is discussed in section 3.4.

Many people are also concerned about the possibility that uranium intended for use in nuclear reactors may be diverted to the production of nuclear weapons or that nuclear fuel waste from the reactors may be used for this purpose. In section 3.5, we examine the steps that Canada and the international community have taken to prevent this from happening.

For some people the concerns described above are serious enough that they believe that the use of nuclear energy to generate electricity should not be continued, and some European countries have taken steps to end their nuclear power programs. On the other side, however, many countries are convinced of the benefits of nuclear power and are building or planning new reactors.

[7] World Nuclear Association website.

3.2 Future for Nuclear Power and Uranium

3.2.1 Outlook for Nuclear Power

According to a report of the International Atomic Energy Agency[8], there were 441 nuclear power plants in operation as of December 31, 2005 and 27 under construction, of which 16 are in Asia, which is the centre of expansion. These plants provided about 16% of the world's electricity. Some recent analyses of the future use of nuclear power predict that there will be a large increase in the use of nuclear power over the next few decades and the rest of this century. According to the Nuclear Energy Institute, 77 new reactors are currently planned or proposed.

A recent book[9] that examines all energy options and makes the case for the sustainable use of fossil fuels predicts nearly a five-fold expansion of nuclear power by the end of the century—to 2000 plants worldwide, with most of the expansion in the latter half of the century. There are plans for a significant expansion of nuclear power in many countries, including India, China, Japan, the Republic of Korea and the Russian Federation. For example, India now has 15 reactors in operation and eight under construction. It intends to have 31 plants by 2020 and many more by 2050. China currently has nine operating reactors and three under construction. It plans to build 30 new reactors by 2020. Japan plans to add ten units by 2014 and double its nuclear capacity by 2050. Plans have also been announced for new reactors in several other countries including Canada, France, Finland, and the United States. Australia, which has no reactors, is currently reviewing the possibility of nuclear power, and some members of the European Union (e.g. the Netherlands) appear to be changing their positions on phasing out nuclear power.

This renaissance in nuclear power is presumably a reflection of how many governments around the world have weighed both the negative and positive aspects of nuclear power and decided in favour of building new plants and extending the active lives of existing ones. In Canada recently, Ontario and New Brunswick have announced plans to refurbish existing reactors and Ontario has plans to build new units. This will put increasing demand for mined uranium as the primary source of fuel for nuclear reactors.

3.2.2 Outlook for Uranium

The market for uranium has historically been subject to very large price fluctuations. From a recent low of just over $7 at the beginning of 2001, the spot price[10] of uranium has risen to around $60 currently. Many analysts expect the price to stay high or increase over the next several years as global demand for energy sources, especially for electricity, increases and secondary sources of uranium are depleted.

[8] Nuclear Technology Review 2006; report by the Director General of the International Atomic Energy Agency; July 2006.
[9] Jaccard, Mark; Sustainable Fossil Fuels, the Unusual Suspects in the Quest for Clean and Enduring Energy; Cambridge University Press; 2005.
[10] Although most uranium is sold under long-term contracts, some is also sold on the "spot market".

While the estimates of the projected future world-wide demand for uranium for nuclear power generation vary widely, it appears that all projections see at least some increase in the demand. A paper by the OECD/IAEA[11] projects an increase in "world reactor-related uranium requirements" of between 22% and 50% by 2025. Much of this increase is projected to take place in the "East Asia" region and the "Central, Eastern and South East Europe" region. The paper notes that "secondary sources [of uranium] are expected to decline in importance, particularly after 2015" and that reactor requirements will have to be met by the "expansion of existing production capability together with the development of additional production centres or the introduction of alternate fuel cycles"[12].

The paper noted that "there are great uncertainties in these projections as there is ongoing debate on the role that nuclear energy will play in meeting future energy requirements." After describing some key factors that will influence future nuclear energy capacity—base load electricity demand, public acceptance and economic competitiveness—the paper states: "Concerns about longer-term security of supply of fossil fuels and the extent to which nuclear energy is seen beneficial in meeting greenhouse gas reduction targets could contribute to even greater projected growth in uranium demand over the long-term."

To summarize, many recent reports indicate that nuclear power will continue to provide an important part of the world's electricity. This demand has driven uranium prices to the current high levels and may drive them higher. In turn, the high uranium prices have sparked a huge increase in exploration for uranium deposits. This will provide opportunities for those places throughout the world—such as Nunavut—that have known deposits of uranium or the geological conditions that suggest the potential for the discovery of new deposits.

3.3 Nuclear Power and Climate Change

Nuclear energy has the capability to produce the base load electricity required to provide a constant and reliable source of electricity to help satisfy the increasing world demand, while avoiding the negative impacts of electricity produced from fossil fuels.

One of the most important positive aspects of nuclear power is the fact that the production of electricity by this means does not emit carbon dioxide to the atmosphere. Thus it does not contribute to global warming and climate change. Of course, some carbon dioxide is emitted during the various activities related to finding, mining and processing uranium ore, chemically refining and converting the raw material and manufacturing fuel bundles and, of course, in building and operating (and eventually decommissioning) the nuclear power plants and storing and disposing of the nuclear fuel waste. However, a study by the IAEA has shown that the total carbon dioxide emissions

[11] Uranium 2005 – Resources, Production and Demand; 2006; Organization for Economic Co-Operation and Development [OECD] and International Atomic Energy Agency [IAEA]; Executive Summary.
[12] This refers to using fuels such as thorium and plutonium in place of uranium.

from the whole life cycle of nuclear power are much lower than that for electricity generated by the combustion of fossil fuels, such as coal and natural gas, and perhaps surprisingly, may even be lower than that for renewable energy, such as hydro, solar and wind. This fact is a result of the immense amount of energy released during the process of nuclear fission.

The burning of fossil fuels results in pollution and the emission of greenhouse gases that are a major contributor to global warming and climate change. Gases such as carbon dioxide and carbon monoxide are called "greenhouse gases" because they concentrate in the earth's atmosphere, where, like the glass in a greenhouse, they help to prevent heat from escaping into space. The increasing concentration of greenhouse gases in the atmosphere is raising the earth's temperature creating a phenomenon known as global warming. This warming will cause many aspects of the climate to change. As the effects of climate change begin to threaten the sustainability of our eco-system, particularly in northern Canada, it will be increasingly important to greatly reduce fossil fuel emissions throughout the world wherever possible.

The recently released Stern review on the economics of climate change[13] shows several models (including from the IEA; page 235) that include nuclear power in the range of solutions that can achieve important reductions in the emission of greenhouse gases into the atmosphere and help avoid potentially catastrophic climate changes. The other approaches include energy efficiency, greatly expanded use of renewable forms of energy and a means of capturing carbon dioxide from the burning of fossil fuels and storing it underground.

Each of these approaches has challenges. The use of renewable energy sources, such as solar and wind, while desirable alternatives to fossil fuels, have limitations because their energy is diffuse (or spread out) and they are not constant sources. Capturing carbon dioxide and storing it underground is theoretically an excellent solution; however, it has not been demonstrated that this can be done on a large scale at an acceptable cost. As mentioned elsewhere, concerns about the increasing use of nuclear power focus mainly on the challenges of waste disposal and nuclear proliferation; the front-end cost of building the reactors is also another concern. Greater energy efficiency—such as more energy-efficient automobiles and houses—can make up a significant portion of the required reduction in greenhouse gases but, according to the Stern review, all of the other approaches will also be needed to some extent.

Producing electricity by nuclear energy in place of fossil fuels in southern Canada and elsewhere in the world can contribute to lower greenhouse gas emissions and, combined with other measures, can help to slow the onslaught of climate change. Uranium mined in Nunavut can contribute to the production of this nuclear power.

[13] Stern Review: the economics of climate change; HM Treasury; 2006; see http://www.hm-treasury.gov.uk

3.4 Disposal of Nuclear Waste on IOL

The lack of a method of disposing of the waste from nuclear reactors—referred to as "nuclear fuel waste"—is often cited as a major drawback of nuclear power. There is currently no Canadian facility for the long-term storage and disposal of such wastes. However, the matter of this storage and ultimate disposal has been studied for many years in Canada and in other countries that have the same requirement.

A comprehensive study on the disposal of nuclear fuel, released by the Nuclear Waste Management Organization (NWMO) in November 2005, recommends an approach in which storage at nuclear reactor sites, centralized storage, and the placing of used fuel in disposal vaults deep in the granite rock of the Canadian Shield—referred to as Deep Geological Disposal—be combined with a management system called Adaptive Phased Management for the future disposal of nuclear fuel waste. If the Government gives the go-ahead, the NWMO will seek a willing community to host the central facilities. Given issues related to the transportation of the waste material, it is likely that the disposal site would be located in Ontario, where most of the waste is produced.

In a 1997 Board resolution, NTI expressed its opposition to the disposal of nuclear fuel waste in the Arctic. The *Uranium Policy* clarifies NTI's position by stating that it would allow only radioactive waste generated by uranium exploration and mining to be stored and disposed of on IOL. This would include tailings and special waste rock as well as low-level radioactive waste, such as equipment and materials used in the mining operation.

3.5 Use of Uranium for Peaceful Purposes Only

Many people are concerned about the potential for exported uranium to be used in the production of nuclear weapons. Canada, one of the first countries with nuclear capabilities to reject the use of nuclear weapons, has had a long-standing policy of preventing the spread of nuclear weapons and encouraging only peaceful uses of nuclear energy. It has entered into international treaties—such as the Treaty on the Non-Proliferation of Nuclear Weapons (NPT)—and bilateral agreements monitored by the International Atomic Energy Agency (IAEA), the Canadian Nuclear Safety Commission (CNSC) and the Department of Foreign Affairs and International Trade (DFAIT) to prevent uranium exported to other countries from enhancing or contributing to nuclear weapons.

The NPT, signed in 1968, prohibits the development of nuclear weapons and/or the transfer of nuclear weapons technology to other states. Canada is an original signatory to the NPT and has centered its own nuclear non-proliferation policy on the treaty's provisions. At present, 187 states are party to the NPT, including all five declared Nuclear Weapons States. Over 550 facilities and several hundred other locations are subject to regular inspection. The NPT establishes commitments to prevent the spread

of nuclear weapons, promote cooperation in the peaceful uses of nuclear energy and achieve nuclear disarmament.

Bilateral trade agreements contain stringent regulations on the use of uranium exported from Canada. For example, nuclear substance possession licences issued in Canada stipulate limitations that are placed on the licensee importing and exporting the nuclear substances which they are authorized to possess.

The Export and Import Permits Act and the NSCA list substances that require authorization before they can be legally exported from Canada. These lists and regulations are administered by DFAIT through the Export and Import Permits Act and by the CNSC under the Nuclear Safety & Control Act (NSCA).

The CNSC is responsible for regulating domestic nuclear facilities and is also charged with administering the country's safeguards agreement. It was set up in 2000 under the new NSCA and its regulations, as successor to the Atomic Energy Control Board which had served since 1946. The following descriptions of CNSC activities are from the CNSC website:

> "The CNSC is responsible for implementing Canada's nuclear non-proliferation policy which contains two broad, long-standing objectives:
>
> 1. to assure Canadians and the international community that Canada's nuclear exports do not contribute to the development of nuclear weapons or other nuclear explosive devices; and
> 2. to promote a more effective and comprehensive international nuclear non-proliferation regime."

Further, the CNSC "through the [NSCA] and corresponding regulations, implements Canada's NPT commitments: not to receive, manufacture or acquire nuclear weapons or other nuclear explosive devices; to accept [IAEA] safeguards on all nuclear material in peaceful uses in Canada; and to ensure that Canada's nuclear exports to non-nuclear-weapon states are subject to IAEA safeguards."

At the global level, the IAEA was established by unanimous resolution of the United Nations in 1957 to help nations develop nuclear energy for peaceful purposes. The IAEA has a complex system of approaches and measures—commonly referred to as "safeguards"—in place to ensure that countries do not use uranium for the development of nuclear weapons. These include:

- Material accountability: tracking all inward and outward transfers and the flow of materials in any nuclear facility. This includes sampling and analysis of nuclear material, on-site inspections, review and verification of operating records.
- Physical security: restricting access to nuclear materials at the site of use.

- Containment and Surveillance – use of seals, automatic cameras and other instruments to detect unreported movement or tampering with nuclear materials, as well as spot checks on-site.[14]

In summary, international treaties and bilateral agreements monitored by the IAEA, the CNSC and the DFAIT ensure that uranium exported to other countries does not enhance or contribute to nuclear weapons.

3.6 Summary

In the preceding sections, we looked at some aspects of the nuclear industry. It is important to remember that the discussion of many of the aspects described—such as the operation of nuclear reactors and the disposal of the waste from these reactors—is to provide the reader with background information on how uranium mined in Nunavut would be used to produce electricity. The siting of nuclear reactors and the disposal of nuclear waste are *not* being proposed for Nunavut. The *Uranium Policy* is mainly about *uranium exploration and mining*. Now we will look more closely at how exploration for uranium deposits is done and how the deposits are mined and the ore milled (processed).

[14] "Safeguards to Prevent Nuclear Proliferation", World Nuclear Association, November 2003.

4 Uranium Exploration and Mining

4.1 History of Uranium Mining in Canada

4.1.1 The Early Years

The first uranium mine in Canada began operations in 1933 at the Port Radium pitchblende deposit along the east shore of Great Bear Lake in the Northwest Territories. At that time, as uranium had little or no commercial value itself, the ore was mined for the extraction of its radium content, used primarily for medical treatments and luminous dials. The Port Radium Mine began producing uranium in 1942 and this continued until the mine was closed in 1960.

The first exploration boom for uranium began in 1947, when the ban on private exploration of radioactive materials was lifted. In 1949, in what was to be the fore-runner of the Saskatchewan uranium industry, development of a uranium mine in the Beaverlodge area was begun. Shortly after that, in 1953, uranium was discovered in the Elliott Lake area of Ontario. The boom ended in 1959 and the uranium industry went into a long period of decline.

The dangers of exposure to uranium and its daughter products were not fully appreciated in the early years of mining and the regulations permitted far higher levels of exposure than they do now. As a result, workers were exposed to unsafe doses of radiation and there is evidence that some subsequently developed cancer as a result of this exposure.

There were also significant environmental impacts associated with past mining operations in Ontario (especially Elliott Lake), Saskatchewan (especially Beaverlodge), and the NWT (Port Radium). These operations were carried out under less stringent regulations in an operating environment that placed less emphasis on safety and protection of the environment, and at a time when potential dangers of radioactivity were not fully appreciated.

4.1.2 The Modern Era

In the late 1960s, the international market for uranium was revived by the development and expansion of nuclear power. The first large-scale Canadian commercial nuclear power station, at Pickering, Ontario, began operations in 1971. In the 1970s, the price of uranium reached more than $43 U.S. per pound.

In Saskatchewan, the rising uranium prices in the late 1960s and 1970s brought a revival of exploration, resulting in the discovery of a number of moderate- and high-grade deposits of a new type—the unconformity-associated type. The Rabbit Lake, Cluff Lake and Key Lake mines began production in the period from 1975 to 1983. Exploration expenditures in the region peaked during this period, resulting in the discoveries of many

other deposits, including Midwest (1978), McClean Lake (1979), and Cigar Lake (1983). Production of uranium peaked in the early 1980s, however, and prices continued to decline throughout the next several years, eventually falling to the $7 range in January 2001 due to the availability of uranium from the dismantling of Russian weapons.

Shortly after its formation in 1988[15], Cameco discovered the very high-grade McArthur River deposit, which went into production in 1999 after a lengthy review process. Currently, Rabbit Lake, McClean Lake and McArthur River are the only producing uranium mines in Canada. The price of uranium has now climbed to around $60 per pound, sparking a global uranium exploration rush.

4.2 Uranium in Nunavut

4.2.1 Overview

In Nunavut, a significant amount of exploration was done during the 1970s and early 1980s. Large parts of the Thelon Basin (Figure 1) outside the Thelon Game Sanctuary, and parts[16] of the Hornby Bay Basin, were staked and explored by more than a dozen major exploration companies. In the early 1970s, Urangesellschaft Canada Limited (UG) discovered an unconformity-associated deposit it named "Lone Gull"—later renamed "Kiggavik"—and in the 1980s found other nearby deposits—the Andrew Lake and End Grid deposits. We discuss the Kiggavik-Sissons project at greater length in the following section.

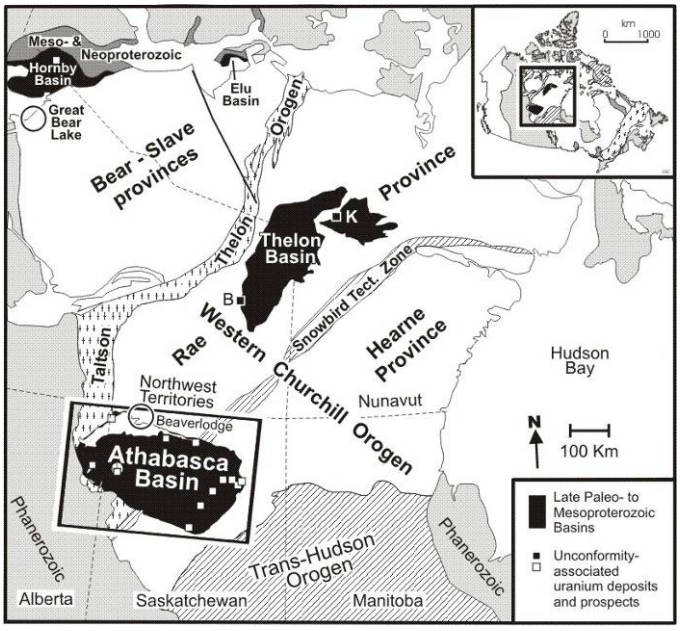

Figure 1. Geological basins (of Proterozoic age) in western Canada with a potential for hosting unconformity-associated uranium deposits. "K" represents Kiggavik. Source: Jefferson *et al.*

In the 1990s, the relatively low grade of the mineralization outlined in the Thelon Basin was overshadowed by the new discoveries in the Athabasca Basin of Saskatchewan. This fact coupled with the decline in uranium prices in the late 1990s and an uncertain

[15] Eldorado Nuclear Limited (formerly Eldorado Mining and Refining) and its subsidiary, Eldorado Resources, merged with the Saskatchewan Mining and Development Corporation (SMDC), a Crown corporation of the Saskatchewan government, to create the privately-owned Canadian Mining and Energy Corporation – Cameco.

[16] Work was concentrated on the area of the exposed basal unconformity.

regulatory environment resulted in companies putting their exploration efforts in this region on hold. Exploration of the Hornby Bay Basin essentially stopped at the same time.

The dramatic increase in the price of uranium from a low in early 2001 has resulted in a very significant increase in uranium exploration over the past three to four years, with a large increase in the staking of claims and the acquisition of prospecting permits. Furthermore there are indications that the Kiggavik-Sissons project has been revived.

4.2.2 The Kiggavik-Sissons Project

To date, there has been no uranium mining and only one proposed mine in the area that is now Nunavut. The Kiggavik-Sissons project, which includes several uranium deposits about 75 kilometres west of Baker Lake, encompasses two discrete projects: the Kiggavik project, now owned 99% by AREVA Resources Canada Inc.[17], which contains the Kiggavik deposit; and the Sissons project (owned 50% by AREVA), which includes the Andrew Lake and End Grid deposits. The area of the mining leases that include these two deposits was subsequently selected by Inuit as a Subsurface IOL parcel during the land selection process. (Although the leases are "grandfathered" under the CMR, INAC will remit all royalties collected from the production of uranium on this parcel to NTI.)

The overall reserves for the three deposits that comprise the Kiggavik-Sissons project are in the order of 50,000 tonnes of uranium (roughly 120 million pounds of U_3O_8) at an average grade of about 0.4% uranium. A 1986 prefeasibility study of the project proposed that the deposits be mined by a combination of open pit and underground methods and that the yellowcake product be transported by truck from the mine to Baker Lake and barged from there.

In 1988, UG completed a full feasibility study and took steps to get the environmental assessment process underway. Local community members as well as individuals and groups from the region and elsewhere in Canada expressed their concern both with the environmental assessment process and the specifics of the proposed project. In March 1990, following a plebiscite in which a large majority of Baker Lake residents expressed opposition to the project, the operator UG decided to delay the project indefinitely.

After becoming operator of the project in 1993, AREVA (known as COGEMA Resources Inc. at that time) carried out diamond drilling and other exploration work on the Sissons part of the project until 1997, the last year of field activity for the company in Nunavut. That year, the company completed a prefeasibility study, the conclusions of which were considered to be negative given the circumstances at that time. In 2000, the company demobilized most of its equipment and fuel supply at the site and has since removed the camp and any remaining materials.

[17] As of June 2005 "AREVA Resources Canada Inc." replaced "COGEMA Resources Inc." as the legal name of the Canadian mining arm of the AREVA group of companies.

In October 2006, AREVA opened an office in Baker. It appears to be that the increase in the price of uranium has created a situation in which, with its Kiggavik-Sissons deposits, AREVA may be considering developing Nunavut's first uranium mine.

4.3 Uranium Exploration, Mining and Milling

Life Cycle of a Mine

The life of a mine can be considered to comprise several stages: exploration, from prospecting and early stage exploration, through evaluation of a potential orebody; development, which includes the construction of the mine; mining and milling (processing) of the ore; and reclamation and decommissioning, including the subsequent monitoring.

None of these operations generally involve high enough radiation fields to cause any immediate threat to health and safety of workers or the public. The main concern is usually with collective dose over long periods of time. We describe each of these stages more fully.

Exploration

Exploration comprises two distinct stages—early-stage exploration, and the evaluation of a potential ore body, which is also referred to as mineral deposit appraisal. (In this paper we will refer to this second more advanced stage as the evaluation stage.) Uranium exploration techniques are very similar to those used to look for other minerals, with the exception that the techniques also include methods – such as radiometric surveys and the testing of rock samples with scintillometers – that measure the natural radioactivity of an area or of samples.

Most exploration techniques have no or negligible effect on the health of the workers or on the environment. However, a worker will come into contact with uranium (and its daughter products) during the handling of rock samples and diamond drill core. There is also a concern that radioactive materials may be deposited on the surface of the land or into water bodies during excavating or drilling processes. Thus, measures must be taken to protect workers and the environment.

Mining

As with exploration, uranium mining—which may include underground and open-pit methods—is basically no different from other kinds of mining, except that it is made somewhat more complicated by the presence of radioactive dust, radon gas and gamma radiation. This potential safety hazard is minimized by using powerful ventilation systems in underground mines and—particularly for high-grade ores—remote-controlled and specially shielded equipment.

As part of the mining process, especially for open pit mines, waste rock above and around the uranium deposit must be removed to provide access to the ore. This rock sometimes contains low levels of radioactive materials, heavy metals or sulphide minerals, such as pyrite. Leaching of sulphide minerals may lead to acid rock drainage. Such "special waste rock" is isolated from the atmosphere in order to prevent any of the undesirable substances from polluting nearly water bodies. It is often returned to the mined-out areas.

Milling

During the milling (also called processing) stage, the ore is crushed and ground to a powder. The uranium is then removed from the rock and put into a saleable product known as "concentrate", which is sometimes referred to as "yellowcake". The wastes from the milling operation are discharged into a tailings management facility (TMF). As the tailings contain most of the radioactivity in the original ore—mostly as radium and radon— operators of uranium mines take great care to ensure that the effluent from the TMF does not pose any danger to humans, plants or wildlife.

Reclamation and Monitoring

In most instances, when a mine is closed and the site reclaimed, the TMF will be covered over or otherwise made stable. However, for some situations, the tailings will require monitoring for many years after the mine has closed. The management of tailings and waste rock is discussed in greater detail in section 4.7.4. Appendix 1 gives more details on the processes described in this section.

4.4 Saskatchewan as a Model for Uranium Mining

As described in section 4.1, Saskatchewan has a long history of uranium mining, extending back to the late 1940s and early 1950s when the Beaverlodge, Gunnar, and Lorado mines were developed. Uranium mining in Saskatchewan has continued to play a large role in the global energy sector and now accounts for about 30% of worldwide uranium mine production. These mines are located in Northern Saskatchewan within the geological feature known as the Athabasca Basin.

There are several reasons why it is useful to examine the recent experience of uranium mining in Saskatchewan in greater detail:

- Saskatchewan currently has the only operating uranium mines in Canada.
- McArthur River is the most recent mine to open in Canada and has the largest production and highest grade of all uranium mines in the world.
- The Cigar Lake mine, the second largest high-grade orebody in the world, has just gone through the permitting process and is under construction.
- The McClean Lake mill is the first new mill in North America in twenty years, and the mill and associated Tailings Management Facility represent the state-of-

the-art for processing ore into uranium concentrate. McClean Lake is also the only northern Saskatchewan operation with open pit mining operations. (See section 1.10 in Appendix 1.)

- The Cluff Lake mine has been almost completely decommissioned, thus serving as an example of how a uranium mine can be decommissioned.
- The Saskatchewan mines demonstrate the most advanced applications of technology and quality management applied to all aspects of the operation.
- Saskatchewan has a comprehensive regulatory framework in place, which includes detailed procedures for environmental assessment.
- The Saskatchewan mining industry pays particular attention to the needs of northerners and consults with residents on both a regular ongoing basis and on specific issues.
- There is a detailed public record of the review process undertaken from the early 1990s up to the present to establish new mines in the region. A wealth of information is available from both private and public sources, including the Federal-Provincial Review Panel and the Federal Government response to the panel reports, which provides an indication of how the Government would deal with or respond to similar issues in Nunavut. Recent environmental assessment documents provide a wealth of information on all aspects of the proposed projects.
- There are similarities between Nunavut and northern Saskatchewan in terms of population, education levels, socio-economic and other factors.
- Inuit have visited the Saskatchewan operations and have an appreciation for the potential benefits and how potential impacts are handled.

By examining the uranium mining industry in Saskatchewan, we can learn a great deal about the entire process through which a mine is developed, operated, and decommissioned. We can also envisage the regulatory framework within which the mining industry operates. Because the Saskatchewan mines have a long track record of technological innovation and environmental protection, they are an excellent model for the uranium industry in Nunavut.

Although environmental regulations, worker safety, and socio-economic standards that would apply to a uranium mine in Nunavut would be similar to those that apply in Saskatchewan, there would, of course, be differences in the two jurisdictions.

For the above reasons, a study of the Saskatchewan operations is essential to provide the information as to how modern uranium mining is carried out and what processes are in place to protect workers, nearby communities, and the environment. In 1999 and again in the fall of 2005, Cameco and AREVA, the two companies operating the Saskatchewan uranium mines, provided tours of their operations for NTI and RIA land managers and executive members. Staff and Board members of the IPGs, Government departments and some Baker Lake residents also visited in 2005. The Nunavut visitors saw that modern uranium mining is highly regulated and controlled (the lead regulator is the CNSC under the Federal Government jurisdiction). They also saw that it can be done safely with no

apparent significant impact on the health of the workers and the local population or on the environment.

Figure 2. NTI and RIA visitors at McClean Lake mine (left) and McArthur River mine in September 2005.

In the consideration of any future uranium mining project in Nunavut, Saskatchewan's experience should be closely studied and, to the extent it is relevant, applied to the Nunavut situation.

4.5 Benefits from Uranium Exploration and Mining

A wide range of benefits could be expected to flow from both exploration and mining activities. Regardless of whether a uranium mine ever goes into production in Nunavut, exploration for uranium deposits is likely to continue for many years. This work provides seasonal employment for many people from the local communities as well as business opportunities for suppliers of good and services. In addition, NTI and the RIAs receive fees with respect to exploration agreements and land use licences and leases.

The potential benefits increase with the scale of the operation, and very significant revenues from taxes and royalties could flow directly or indirectly from any uranium mining operation in Nunavut. We can get an idea of the potential impact from economic modeling carried out separately by NTI and the Government of the NWT (GNWT) for gold and base-metal mines.[18] According to the results of NTI's modeling, a low-profit mine might pay royalties of $35 to $40 million and a high-profit mining operation would be expected to pay royalties of up to $80 or $90 million over the life of the mine. For very rich orebodies, , the royalty could possibly be much higher[19]. If the mine is on Subsurface IOL, the royalty would be received by NTI, and if on lands for which the

[18] We do not have access to economic models for uranium mines in the North.

[19] The McArthur River Mine in Saskatchewan provides an example of the royalties and taxes that can flow from a very profitable uranium mine. For this mine, the total government revenues over the 20-year life of the mine are estimated at about $1.4 billion to $3.7 billion dollars (according to the 1997 Panel report), more than the amount of cash Inuit received under the NLCA. It is unlikely that many uranium mines will be as rich or as profitable as the McArthur River Mine, possibly the richest in the world.

Crown owns the minerals, the royalty would be received by the Federal Government, and a percentage of that would be paid to Nunavut Trust.

The GNWT economic models (Bullen, 2003[20]) show similar results. Sherlock et al[21] summarized the results of the modeling and noted that for a diamond mining operation, "royalties in excess of $600 million over a 25 year mine life are possible." It should be pointed out that this model is "influenced somewhat by the world-class Ekati and Diavik operations in the Northwest Territories", thus not all diamond mines would be expected to pay out royalties of this magnitude. The report continues, "…gold operations are somewhat smaller but could provide about $60 million over a 15-year mine life. Similarly, a base metal operation could provide $20-25 million in royalties over a 20-year mine life." Both the NTI and GNWT models demonstrate the range of royalties that might flow from a mining operation in the north. A uranium mine could be expected to return similar royalties. (It should be kept in mind, that these are only models and that actual operations may provide different results.)

Mining operations are also a big source of government taxes. According to NTI's models, the Nunavut Government would receive an amount of taxes approximately equivalent to the royalties described above and the Federal Government would receive roughly twice this amount in taxes. Taxes paid to the Nunavut Government would help to provide benefits to Nunavummiut, such as improvements in housing, education, and health care.

Perhaps of most importance to the people who live in the area of a mine are the potential benefits that would flow to local residents and businesses. A mining operation could provide many years of steady, well-paid work for hundreds of employees. For an operation on IOL (Surface or Subsurface), the RIA and the company would enter into an Impact and Benefit Agreement (IIBA), which would ensure that many jobs and business opportunities would go to Inuit in the local communities[22] and the region. The community may also benefit from improvements to the local infrastructure, such as roads or docks.

NTI's *Mining Policy* already requires that to the greatest extent possible the benefits of mining will remain in Nunavut. The *Uranium Policy* sets out some additional measures that will help Inuit to maximize the benefits. These apply not just to uranium but to other commodities as well.

[20] Bullen, W. and Zhang, J.; 2003; The economics of mining projects in the Canadian Arctic. *In* Proceedings, Seventh International Symposium on Mining in the Arctic; CIMM, pp. 3-18.
[21] Sherlock et al, ibid.
[22] If the mine is on Crown land, Article 27 of the NLCA requires that the proponent consult with the DIO—NTI—with respect to employment, contracting and many other matters.

4.6 Uranium Potential on Inuit Owned Lands

In this section, we refer to some types of uranium deposit and describe where we think uranium deposits are most likely to be found. (Some technical terminology is used.) The Canadian Shield—an area of old rocks which makes up about half of the area of Canada— is one of the largest storehouses of mineable uranium resources in the world. There are many kinds of uranium deposits, but most of Canada's resources are in two types—paleoplacer and unconformity-associated deposits. The former occur mainly in the Elliot Lake area of Ontario and the latter occur mainly in the Athabasca Basin, which is a large area of sandstones and other flat-lying rocks in northern Saskatchewan. This area is the world's premier uranium district because of the large quantities of high-grade resources of the unconformity-associated type.

Because of the geological similarities between the Athabasca Basin and certain areas of Nunavut, uranium exploration in Nunavut has focused on unconformity-associated deposits. Such deposits are formed as a result of geological changes that occur close to major unconformities between older "basement" rocks and overlying younger undeformed sandstones of Proterozoic age. These deposits constitute approximately 33% of the world's (excluding Russia and China) uranium resources, including some of the largest and richest deposits. The high-grade deposits are exceptionally valuable and profitable to mine.

Although the uranium potential in Nunavut is still very much unproven, there is considered to be excellent potential for the discovery of unconformity-associated uranium deposits in two areas of Nunavut—the Thelon Basin near Baker Lake, and the Hornby Bay Basin south of Kugluktuk. There may also be potential elsewhere, such as in the Elu Basin south of Cambridge Bay (see Figure 1). The Kiggavik-Sissons deposits west of Baker Lake and at least some of the occurrences in the Hornby Bay Basin are of the unconformity-associated type. Uranium exploration in Nunavut is mainly focused on discovering deposits of this type.

As noted in section 1.1, some parcels of Subsurface IOL are considered to have good potential for the discovery of uranium deposits.[23] The *Uranium Policy* recommends that NTI carry out a comprehensive assessment of the uranium potential of these parcels (as well as Surface IOL) in order that it and the RIAs can better plan for the use of the lands. Furthermore, such an assessment would assist NTI in enhancing the terms of the agreements it makes with mining companies, including the optimum terms for a participating interest in future uranium mining projects on these parcels.

4.7 Impacts of Uranium Exploration and Mining

[23] Parcel BL-22 has the Andrew Lake and End Grid deposits that make up part of the Kiggavik-Sissons project.

The potential impacts of any development activity, including mining, can be considered to fall into two broad categories—ecosystemic or socio-economic. According to a guide[24] written by the Nunavut Impact Review Board, "Ecosystemic impacts refer to impacts relating to the complex of a natural community of living organisms and its environment, functioning as an ecological unit in nature. Socio-economic impacts refer to social and economic impacts, including impacts upon the local economy, health, demographics, traditional way of life, cultural well-being, social life, archaeological resources, existing services and infrastructure, and community and local government organizations."

In the *Uranium Policy*, some potential socio-economic impacts of uranium exploration and mining are considered in Objective 3, which deals with the protection of human health, and to some extent in Objective 5, which is concerned with community participation. Under Objective 4, the policy considers some aspects of ecosystemic impacts, including impacts on wildlife and the management of tailings and waste rock. It also considers the regulatory processes that are in place to limit and deal with impacts.

4.7.1 Protection of Human Health

Exposure to uranium and related radioactive elements such as radon can be dangerous to human health (see section 2). Because of this radiation danger as well as related non-radioactive impacts, uranium mining requires special consideration beyond that required for other types of mining. The greatest concern is about direct exposure of mine workers and others in the vicinity of the mine to radioactivity. (More detailed information is given in Appendix 1.)

The result of this special attention is that uranium mining is the most highly regulated type of mining in Canada and precautions are taken to ensure that no worker is exposed to radiation above limits. Indeed, because of the elaborate measures to provide a clean dust-free environment and the constant monitoring of workers and the working environment, workers in Saskatchewan's uranium mines normally receive less than 5 mSv per year – not much above the natural background levels of about 2.4 mSv per year, and far below the maximum permissible limit of 50 mSv per year or 100 mSv over five years established by the CNSC in accordance with international standards. As a result, uranium mining would be expected to have no more impact on the health of workers than other types of mining or similar industrial activities.

In addition to the concern about direct exposure to radioactivity at the mine, there is also a concern about the possible impact on the health of those in the communities and at greater distance through the indirect process of taking up radioactive substances from the environment (e.g. water and air) or by eating contaminated plants or animals. This impact is dealt with through the management of the emissions from the mine. In section 4.7.4, we consider the management related to tailings and waste rock.

[24] Guide to the Nunavut Impact Review Board.

As would be expected, the potential exposure to workers during exploration is much less than during mining operations. Potential impacts during the early exploration stage include exposure of workers to radiation while carrying out diamond drilling, trenching and blasting, or otherwise handling rock samples containing uranium mineralization. There is also the possibility that other people may come into close proximity with stored diamond drill core that includes radioactive substances.

For the evaluation stage, activities are regulated by the CNSC under the UMMR. For early-stage exploration, the UMMR are not applicable. Nevertheless, many companies use procedures based on exploration guidelines developed for use in Saskatchewan. Specific measures employed by the companies mining uranium in Saskatchewan to protect workers should, if appropriate for the specific circumstances, be adopted in Nunavut. The *Uranium Policy* recommends the development or adoption of uniform procedures.

The safety and environmental record of the mining of high-grade uranium deposits in Saskatchewan demonstrates that it is possible to have a mining process that is safe for the workers and the local communities and that protects wildlife and the environment.

4.7.2 Regulatory Requirements

Any proposed uranium project would be subject to all of the regulatory requirements that apply to exploration and mining for other substances, including the conformity requirements of land use plans established by the NPC and the impact assessment process of the Nunavut Impact Review Board (NIRB). In addition, there are special requirements for uranium mining. We examine the requirements in greater detail.

Land Use Plans

All exploration and mining activities in Nunavut must conform with the land use plan for that region, if one exists. The Keewatin Regional Land Use Plan says that uranium mining will not be permitted until the matter is thoroughly studied by the co-management bodies and such mining is supported by the people of the region. NTI supports efforts to clarify exactly how these statements are to be interpreted and how the requirements will be implemented.

Environmental Assessment of Projects

With respect to the environmental assessment of projects, the NLCA provides for a comprehensive screening and review process for all project proposals. NIRB screens all proposals to determine whether a review is required and, if so, to highlight the ecosystemic and socio-economic impacts that are likely to ensue from the project in question. A review of a uranium mining proposal would be done by NIRB under the requirements of Part 5 of Article 12 of the NLCA, or, under Part 6, by a federal environmental assessment panel. The environmental assessment process is very

comprehensive and provides many opportunities for Inuit to participate. An environmental assessment under the Canadian Environmental Assessment Act would also be required by the CNSC, although it is possible that it could be done in conjunction with the NIRB assessment.

Regulation of Operations

The operations of a uranium mine or the evaluation of a potential ore body are regulated by the CNSC under the Nuclear Safety and Control Act (NSCA) and its regulations. As the federal government regulator, the CNSC has clear jurisdiction over nuclear materials and activities in Canada. The regulations under the NSCA apply to any activity involving the handling of a nuclear substance, including the transportation of radioactive samples. The Uranium Mines and Mills Regulations (UMMR) apply at the evaluation stage after a deposit of uranium has been discovered and is being evaluated to determine its economic viability and for all other mining activities through to closure of the mine.

Land Use, Water and Other Permits

There are many regulations that apply to an exploration or mining project. A review of the regulations that apply to Crown land is presented in *Exploration and Mining on Crown Lands in Nunavut Guidebook*, published by INAC. With the exception of regulations and policies that are specific to Crown lands (e.g. the Territorial Lands Act), all of the requirements also apply to IOL.[25]

At this time there are no uranium-specific requirements in land use licences or leases issued by the RIAs for exploration or mining. The *Uranium Policy* recommends that land use terms and conditions be developed or adopted. As an initial step, measures used by uranium companies in Saskatchewan to protect people and the environment during early stage exploration should be reviewed, and to the extent they are applicable, adopted for use on IOL.

Financial Security

To ensure that reclamation of a minesite is carried out after the mining operations have ended, the operator must provide financial security before a mine begins operations. For a uranium mine on IOL, financial guarantees may be required by: CNSC under the NSCA; the Nunavut Water Board for water permits (security held by INAC); and the RIA, with respect to land use under a commercial lease. The role of the RIA in shouldering liability and holding security with respect to a uranium mining operation would need to be thoroughly examined and resolved in the project review process.

Thus, NTI supports the existing regulatory processes, but has identified areas of concern (some of them outside the regulatory processes) where it will require that special attention be paid. The policy also identifies measures that NTI and the RIAs will take with respect to the management of IOL.

[25] NTI is currently drafting a similar guide for IOL.

4.7.3 Wildlife

An important concern for many people is the possible impact a uranium mine could have on caribou and other animals and plants in the area. Many of the concerns that must be addressed are essentially the same as those for an operation that is mining other commodities, such as gold or diamonds. These include the impact of the minesite itself and related infrastructure, such as roads, on the activities of the animals.

In discussing the future of caribou, a report[26] of the Beverly and Qamanirjuaq Caribou Management Board (BQCMB) identifies roads, exploration and mining, including the potential cumulative effects, as land use activities that pose the greatest threat to the Beverly herd. The Qamanirjuaq herd also faces the threat of hydro-electric development. According to the report, activities associated with mining which have potential negative effects on caribou include frequent low-level aircraft flights, construction of roads and airstrips, frequent travel by supply trucks, mine construction and operation, and pollution of land and water by toxic substances. The report stated that these activities can result in loss of habitat, increased human access, and disturbance to caribou; roads may also act as a barrier if traffic volume is high or plowing creates snow walls. It also expressed a concern that climate change may have a large impact on the caribou.

Concern about the possible impact of uranium mining is not limited to the physical impact of the operations on caribou and other mammals. There is also a worry that radioactive and other potentially toxic substances could enter the food chain and be taken up by caribou and other mammals, fish and birds and the smaller organisms on which they feed and eventually be consumed by humans. There are similar concerns about plants, especially those that produce edible berries. It is not only mining operations that concerns people. In correspondence to NTI[27], the BQCMB identifies "the effects of radioactive dust" and "damage to vegetation and water sources from contamination or physical alteration" as potential impacts from exploration.

In considering the possibility that wildlife may become ill or contaminated by ingesting material contaminated with radioactivity derived from a uranium mining operation, it is informative to look at the findings from environmental monitoring by community groups near Northern Saskatchewan communities. The monitoring found no significant effect of the mining operations, even for samples taken from the area around the community of Wollaston Lake near the Rabbit Lake mine. The report of sampling for Wollaston Lake found that "[a]ll key parameter levels in fish, plants, and wildlife were low and gave no indication that they would not be safe to eat with respect to these parameters."

It is also of interest that the Arctic Study found that caribou in Canada's Arctic have higher than expected levels of radioactive substances. The study attributes this not to any

[26] 20th Anniversary Report of the Beverly and Qamanirjuaq Caribou Management Board
[27] Letter dated May 1, 2006, providing comments on the draft Uranium Policy and draft Consultation Document.

global uranium mining but to the fallout from nuclear testing and the Chernobyl accident, events from the 1970s and 1980s. Caribou apparently show no ill effects from these elevated levels, nor do the people who eat the caribou.

All concerns about the impacts of mining on caribou and other wildlife and plants would be fully addressed in any future environmental assessment of a uranium mining project, which would require that all potential impacts be considered and resolved. The assessment process should require extensive monitoring and testing of wildlife and plants in the vicinity of the mine to ensure that these were not being exposed to radiation or being affected by the mine in any other way. Caribou protection measures, which are currently in place to further protect caribou during the calving and post-calving periods, would also have to be respected.

4.7.4 Management of Tailings and Waste Rock

Mine wastes and tailings contain rock brought from underground to the surface. Waste rock is broken and includes material of all sizes; tailings are crushed and ground to the consistency of sand or silt. This process may bring deleterious substances such as radioactive substances, heavy metals or other undesirable metals, and acid-generating minerals into contact with the atmosphere and with humans. Although radioactive substances will slowly become less radioactive and other minerals will stabilize with time, much of this material will be a potential hazard for many years – for some substances, virtually forever. As the obligation to protect human health and the environment applies to future generations as well as the present ones, measures must be implemented to minimize the hazards from these materials.

The industry's long-term goal is to return the site of the operations as close as possible to a natural state suitable for future uses. All operating mine sites must post financial security to ensure adequate funds are available for proper decommissioning of each mine site after the ore has been mined out. The long-term management of special waste rock (rock that contains substances that could cause some environmental harm[28]) and tailings requires particular attention. Special mine wastes are normally returned back to the mine after the operation has ended, and tailings are commonly deposited in open-pits from which ore has been removed and which have been specially engineered to receive them. Appendix 1 describes in greater detail some of the measures currently employed at Saskatchewan mines.

The long-term monitoring of any special waste rock and tailings that remain after a mining operation has ended will likely be necessary to protect future generations from unacceptable impacts related to these materials. The possible need for such monitoring of these materials, particularly the tailings, would receive special consideration in the assessment of any uranium mining proposal. Furthermore, the CNSC requires that a fund be established to finance the long-term monitoring and possible remediation of tailings facilities and that an authority be set up to oversee it.

[28] See Appendix 1, section 1.6 for more information.

CNSC Regulatory Policy P-290 (2004) describes the principles that are taken into account by the CNSC "when making a regulatory decision concerning radioactive waste management". Furthermore, the draft *Reclamation Policy* being developed by NTI and the RIAs for application to IOL includes principles for the reclamation and decommissioning of a mining operation on IOL. Although DIAND's *Mine Site Reclamation Policy for Nunavut* applies mostly to developments on Crown lands, there may be some aspects that would also apply to a mining operation on Surface IOL.

The *Uranium Policy* recommends that matters related to tailings and special waste rock, including the possible need for long-term monitoring, receive special consideration in any uranium mining proposal. It also recommends the involvement of the people of the affected communities in the environmental monitoring of uranium mines in Nunavut, for both operating mines and for the period after the mines have ceased operations and have been decommissioned.

4.8 Community Participation

Socio-economic Matters

In addition to concerns about human health, the environment and wildlife (that is, the ecosystem), there are also socio-economic matters to consider. As described in section 4.5, there may be many economic benefits from a uranium mine. The NLCA guarantees that Inuit will have an opportunity to participate in those benefits. Nevertheless, there are concerns about the impact of economic development on Inuit culture, way of life, and community well-being. These concerns must be addressed if Inuit are to take full advantage of the economic opportunities.

Communication and Consultation

In addressing the potential impacts—and the benefits—of a project, it is vital that the project proponent or operator communicate effectively with community members. The failure of both parties to do so may result in an inadequate environmental assessment process and concerns and misunderstandings about the impacts and benefits which may continue during the operating phase of a mine. In part, this may be a result of insufficient attention paid by the proponent/operator to the community consultation process, but it can also be due to the challenge of communicating details about the scientific and technical aspects of the operation.

NTI	Nunavut Tunngavik Incorporated
RIA	Regional Inuit Association
UMMR	Uranium Mines and Mills Regulations

Appendix 1 Exploration, Mining and Milling of Uranium

1.1 Introduction

The life of a mine can be considered to comprise several stages: exploration, from prospecting through evaluation of a potential ore body; development, in which category we include planning, permitting, siting and construction; mining and milling (processing) of the ore; and reclamation and decommissioning, including the subsequent monitoring. Each of these stages entails many different processes. In this appendix[29], we present additional information to supplement that provided in section 4.3. This brief overview includes the processes involved in these stages, the risks relating to the health and safety of the workers and local populations, the impact on the environment, and the methods employed to minimize these risks.

1.2 Exploration

1.2.1 How Exploration is Done

Exploration for uranium deposits uses most of the same techniques employed for finding deposits of other metals. The main difference is that uranium exploration includes methods to detect radioactivity that results from the decay of the uranium.

Exploration methods include prospecting, boulder tracing, rock sampling, and geological mapping, all of which include the use of a scintillometer carried by the worker to detect uranium. Other standard methods include geochemical methods to detect uranium and related elements in soils, unconsolidated surficial deposits, vegetation and water. This process is sometimes also done with the assistance of a "reverse circulation drill" which collects samples of surficial materials at depth. In all these methods, samples are collected and sent away for analysis.

Geophysical methods include both ground and airborne surveying, using both direct methods to detect radioactivity and indirect methods, such as magnetic, electromagnetic and gravity surveys to indicate favourable geological conditions.

After these various surveys have indicated anomalies which suggest the possible occurrence of a uranium deposit, the anomalies are tested by diamond drilling. As with exploration for other commodities, such as gold or zinc, the drilling extracts a core of the bedrock. The core is examined and, if a part of it looks encouraging, this section is split into two halves, one of which is sent away for analysis. The un-split core plus the remaining half of the core that was split are stored on the site in core boxes and placed on core racks or in stacks.

[29] The information is extracted from an internal NTI report titled "Discussion Paper – Policy Concerning Uranium Mining In Nunavut", 2005.

On some projects, pits and trenches may be excavated so that samples can be taken. For the evaluation stage of exploration projects, the deposit may be explored underground by way of a shaft or decline.

1.2.2 Health and Safety and Environmental Measures

Most of the exploration techniques described above have no or negligible effect on the health of the workers or on the environment. However, a worker will come into contact with uranium (and its daughter products) during the handling of rock samples and diamond drill core. Furthermore, there is a potential that radioactive materials may be deposited on the surface of the land or in water bodies during excavating or drilling processes.

Companies carrying out uranium exploration undertake many measures to protect human health and the environment, including:

- all persons working at the exploration site must wear a gamma radiation dosimeter;
- no person shall be exposed to a whole body dose of more than 1 millisievert (mSv) in a 12 month period unless classified and trained as a Nuclear Energy Worker (NEW); the CNSC limit for a NEW is 50 mSv per year or 100 mSv over a 5-year period;
- in areas where radon gas may accumulate, monitoring equipment will be used and work areas are to be well ventilated;
- all workers are given safety instructions so that they will minimize their exposure to radiation;
- all diamond drill holes are "probed" with instruments and the core is checked for radioactivity;
- where drilling encounters radioactive rock intervals, these intervals in the holes are sealed with concrete so that there will be no discharge of radioactive waters into the environment;
- all drilling waters are re-cycled and re-used to the greatest extent practicable; this minimizes the release of radioactive waters to the environment
- care is taken that no materials contaminate the water supply;
- radioactive diamond drill cuttings are separated out from the drill water, collected in bags and drummed for future shipment for processing or disposal;
- after the drill has been moved from a site, the site is checked to ensure safe levels of radioactivity; when needed, contaminated material is cleaned up.

Exploration for uranium is subject to all of the other regulatory requirements that would apply to exploration for any other minerals, including environmental assessment, water licences, land use permits and licences and conformity with land use plans.

1.3 Mining

1.3.1 How Mining is Done

Generally speaking, uranium mining is no different from other kinds of mining except that it is complicated by the presence of elevated levels of gamma radiation, radioactive radon gas, and dust containing low levels of radioactivity. These potential safety hazards are minimized by the well-known principles of time, distance and shielding to minimize exposures to gamma radiation, and by using powerful ventilation systems in underground mines to control radon levels and dust. For high grade ores, remote-controlled and specially shielded equipment is also used.

Where ore bodies lie close to the surface, they are usually accessed by open-pit mining, involving a large pit and the removal of much overburden as well as a lot of waste rock. The Kiggavik-Sissons deposits are close to surface and would be mined mainly by such methods. In Saskatchewan, after the ore bodies are mined, such pits are used for the permanent storage of tailings and for some types of waste rock which pose potential long term environmental risks if left permanently.

Figure 3. Deilmann open pit at Key Lake mine, in 1994. In 1996, the pit was converted to a tailings management facility and now receives tailings from the McArthur River mine.

Where ore bodies are deeper, underground mining is employed, involving construction of access tunnels and shafts but with less waste rock removed and less environmental impact. The McArthur River mine and the Cigar Lake mine (currently being developed) are underground mines. Some mines, such as the McClean Lake mine in Saskatchewan, employ a combination of open-pit and underground mining.

In the United States, Australia, Kazakhstan, and elsewhere, a mining method called *in-situ leach* (ISL) mining is used. Some ore bodies lie in groundwater in porous unconsolidated material and may be accessed simply by oxygenating the groundwater and making it more acidic or alkaline so that it dissolves the uranium. The groundwater solution, with the dissolved uranium, is then pumped to the surface, where the uranium is recovered at a treatment plant. This method, which is not used in Canada, would not be applicable to Nunavut.

Over half of the world's primary uranium production now comes from underground mines, about 27% from open-pit mines and 19% from ISL.

1.3.2 Health and Safety and Environmental Measures

The practices of the 1940s and 1950s in which miners and other workers in the uranium mining industry were exposed to dangerous levels of radioactivity is thought to have contributed to a high incidence of cancer and other diseases among these workers. This is particularly true of the miners who worked at Port Radium in the NWT and at the Beaverlodge mines in Saskatchewan. Our discussion will deal only with modern mining methods, which are many times safer than the old practices.

Most hazards associated with uranium mining are common to the mining of other substances. Uranium itself is only slightly radioactive. However radon, a radioactive gas, is released to the atmosphere in very small quantities when the ore is mined and crushed. Although radon occurs naturally in most rocks and minute traces of it are present in the air which we all breathe, at the relatively high concentrations associated with uranium mining, radon is a potential health hazard.

Special precautions taken during the mining and milling of uranium ores to protect the health of the workers include:

- Efficient dust control, because the dust may contain radioactive constituents and emit radon gas.
- Limiting the radiation exposure of workers in mine, mill and tailings areas so that it is *as low as reasonably achievable* (ALARA principle), and in any event does not exceed the allowable dose limits.
- The use of specially shielded equipment by miners to reduce exposure to radiation. Mining of very high-grade ore is undertaken solely by remote control techniques.
- The use of radiation detection equipment in all mines.
- The use of good forced ventilation systems in underground mines to ensure that exposure to radon gas and its radioactive daughter products is ALARA and does not exceed established safety levels. The radon is diluted in very large volumes of air and released into the atmosphere.
- Imposition of strict personal hygiene standards for workers handling uranium oxide concentrate. (Uranium oxide has a chemical toxicity similar to that of lead oxide if it is ingested. Similar precautions to those in a lead smelter are taken when handling it.)

The McArthur River mine in Saskatchewan – which has very high-grade ore – uses remote, "non-entry" mining methods. Measures include remote underground crushing and grinding facilities, transportation of ore in shielded containers and the use of specially shielded receiving stations at the mill. Worker exposure to the high-grade ore is virtually eliminated[30]. The Cigar Lake mine will employ similar measures.

[30] Natural Resources Canada, Energy Sector web site.

1.4 Milling of Uranium Ore

1.4.1 How Milling is Done

After ore is removed from the ground, either by underground mining or from an open pit, it is milled. The milling process, in which the ore is crushed and treated with chemicals, extracts the ore's uranium content, leaving a waste product known as mill tailings. The process is illustrated in the following figure.

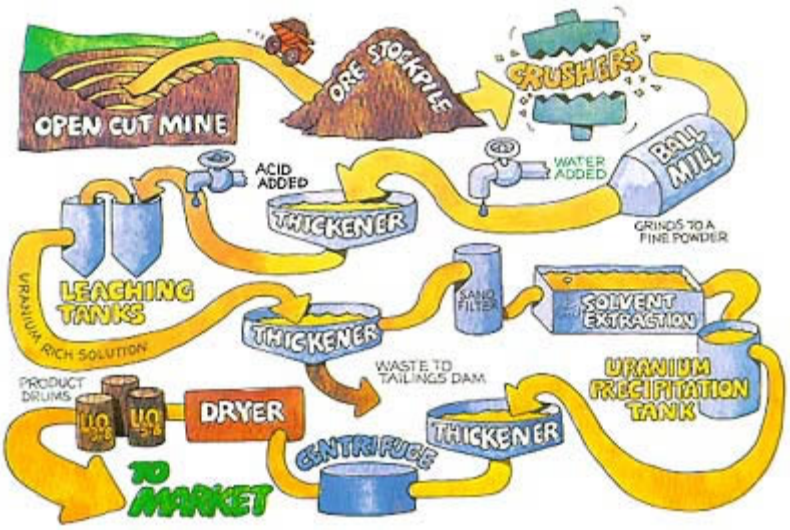

Figure 4. Overview of the milling process. Source: World Nuclear Association web site.

In Saskatchewan's McArthur River mine, the crushing and grinding part of the milling process takes place underground at the mine and the resulting ore slurry is trucked in containers to an off-site mill (Key Lake mill) where the rest of the milling process takes place.

Figure 5. Key lake mill processes ore from McArthur River mine. Tailings are deposited in the Deilmann open pit. Source: Cameco Corporation.

At the McClean Lake mill, run-of-mine ore from the open pit mines is received into the mill grinding circuit. Most of the ore – that is, the part remaining after the uranium has been dissolved – remains un-dissolved in the leaching process, and these solids or 'tailings' are then separated from the uranium-rich solution in a series of tanks where the washing solution flows through the tanks in one direction and the washed solids are

moved in the opposite direction. The liquid containing the uranium is filtered and the uranium then separated from other impurities dissolved from the ore using a solvent extraction process.

Finally the uranium is recovered in a chemical precipitate which is filtered and dried to produce a uranium oxide concentrate, or "yellowcake", about 99% U_3O_8. The yellowcake is then packed into "45-gallon" steel drums which are sealed for shipment. The U_3O_8 is only mildly radioactive: the radiation level one metre from a drum of freshly-processed U_3O_8 is about half that from cosmic rays (from the sun) on a commercial jet flight. The tailings solids from the leach circuit are combined with other waste streams in the tailings preparation circuit, further treated with reagents to achieve the desired characteristics and pumped to the tailings management facility (TMF).

Figure 6. Left - Yellowcake is produced at the mill and sent to Blind River for further processing or exported. Right - Barrels of yellowcake ready to be shipped.

1.4.2 Health and Safety and Environmental Measures

Most of the discussion dealing with health and safety issues relating to mine workers is also relevant to workers in the uranium mills. The main concerns in the mill as in the mine are dust (containing radioactive particles), radon gas and gamma radiation (primarily from the ore, not from the uranium after it has been separated from the tailings). The dust is collected and fed back into the process. Radon gas is diluted and dispersed to the atmosphere in large volumes of air.

The main environmental concern is the discharge of "contaminated" water from the milling process. According to a report by the CNSC[31], "[t]he volume of water that is generated from mining and milling processes is too large to be stored indefinitely. At most mines a portion of this water can be reused in the milling process; however, much of it must be discharged to the environment. Before this can happen, the water is treated by the addition of certain chemicals. For example, barium chloride is added to remove

[31] Canadian National Report for the Joint Convention on the Safety of Spent Fuel Management and on the Safety of Radioactive Waste Management; Produced by the Canadian Nuclear Safety Commission; May, 2003.

radium by precipitation. The water discharged from uranium mines and mills in Canada is monitored to ensure that it meets limits on chemical concentrations that have been prescribed by the Canadian government. These limits ensure that the impact on the environment is minimal. Recently, legislation has been introduced to require that these discharges are not acutely toxic to fish."

1.5 Radioactivity in Mining and Milling Wastes

The earth naturally contains a variety of radioactive materials – uranium, thorium, radium and the radioactive gas radon. The mining and milling of uranium and some other ores brings these radioactive materials into closer contact with people, and in the case of radon and its daughter products, speeds up their release to the atmosphere.

Residual wastes from the milling operation contain the remaining radioactive materials from the ore, such as radium. These wastes are discharged into tailings management areas designed to retain the remaining solids and prevent any seepage of the liquid. Eventually the tailings may be put back into the mine or they may be covered with rock and clay, then re-vegetated.

The radioactivity content of the tailings is approximately the same as in the original ore, and is primarily associated with the solids. That is, the radioactive elements were either not dissolved, or were largely precipitated in the tailings preparation circuit. Uranium oxide (U_3O_8) produced from the mining and milling of uranium ore is only mildly radioactive – most of the radioactivity in the original ore remains at the mine site in the tailings. The various radioactive isotopes have half lives ranging from fractions of a second to minutes, hours or days, through to billions of years. Radioactivity decreases with time as these isotopes decay into stable, non-radioactive ones. The rate of decay of an isotope is inversely proportional to its half life; a short half life means that it decays rapidly. Hence, for each kind of radiation, the higher the intensity of radioactivity in a given amount of material, the shorter the half lives involved.

Three general principles are employed in the management of radioactive wastes of all levels:

- Concentrate and contain
- Dilute and disperse
- Delay and decay.

The first two are also used in the management of non-radioactive wastes. The waste is either concentrated and then isolated, or it is diluted to acceptable levels and then discharged to the environment. "Delay and decay", however, is unique to radioactive waste management; it means that the waste is stored and its radioactivity is allowed to decrease naturally through decay of the radioisotopes in it.

1.6 Management of Waste Rock

The two main waste streams associated with uranium mining and milling are tailings and waste rock. Tailings are managed in engineered TMFs, as described in the following section. Waste rock is material that must be removed from the deposit in order to gain access to the ore. This material can amount to millions of cubic metres of rock, especially at an open pit mine. Some of this waste rock could actually be mineralized material that is low-grade ore or contain high concentrations of accessory minerals. The cut-off grade for benign waste rock is typically 0.03% uranium, with material greater than 0.03% but less than an economic grade defined as "special waste."

"Acid rock drainage" (ARD) means low pH (that is, acidic) surface or ground water that results from the oxidation of sulphide minerals or the dissolution of acid-generating minerals found in rocks and coal. This ARD, if it finds its way into nearby water bodies, can acidify these and create a toxic acidic environment. It can also dissolve other metals in the waste rock and allow these to enter into the environment.

The CNSC report on the Cigar Lake environmental assessment says, "In Saskatchewan, some waste rock contains secondary arsenic and nickel minerals, often to the point that it is the long-term care and control of these non-radioactive contaminants that drive the level of care needed to manage the waste rock, not its radioactivity." Molybdenum and selenium levels are also a concern at some mines and require special treatment, as is the case at the Cigar Lake mine now under construction.

Historically, waste rock has been stockpiled on the surface or used as backfill in underground mines. However, if left exposed on the surface indefinitely, some of this "special waste rock" could generate acid or release metals at rates that could harm the environment. The current method of managing special waste rock is to isolate it from atmospheric conditions (e.g., locating it at the bottom of a flooded pit).

1.7 Management of Tailings

1.7.1 Introduction

Solid waste products from the milling operation are pumped as a slurry of solids and liquids to a TMF as described in section 1.5. The solids consolidate – as a silty or sandy material – and the water, or effluent, drains off.

Operators of uranium mines take great care to ensure that the tailings they produce do not cause damage to the environment. The waste management objective is to control and limit the release of potentially harmful substances from the TMF into the environment. Care is taken to ensure that the effluent from the TMF does not pose any danger to humans, plants or wildlife. The effluent is treated and tested before it is released into the environment to ensure that it meets all water standards.

1.7.2 Nature of the Tailings

The solid tailings that settle out from the slurry in the TMF are generally similar in composition to the ore that was originally extracted from the ground, but also contain some secondary minerals and chemical precipitates introduced in the milling process.

As with tailings from other types of mining, such as gold mining, tailings from a uranium mine may contain heavy metals that were not extracted during the milling process. (In this way, the tailings are similar to special waste rock as described in section 1.6). In the Saskatchewan mines, these may include nickel, arsenic, molybdenum and selenium. They may also contain sulphide minerals such as pyrite that can result in the generation of acidic waters in the effluent that leaves the tailings facility.

Of particular significance to this paper, however, tailings from a uranium mine may contain small amounts of radioactive minerals or the dissolved gas, radon. Tailings comprise most of the original ore (i.e. rock that has been processed in the mill) and they contain most of the radioactivity in it. In particular they contain radium that was present in the original ore. When radium undergoes natural radioactive decay one of the products is radon gas. Because radon and its decay products are radioactive, measures are taken to minimize the emission of radon gas.

The solid tailings contain no more hazardous substance than the original rock, but their chemical form has often been modified. Although the substances may, as a consequence, be more mobile (i.e. can be dissolved in groundwater and surface waters), the fact that they have already been subjected to strong leaching conditions in the milling process means that such residual minerals are not easily leached in the less aggressive natural conditions in the TMF.

1.7.3 Management of Tailings

Historically, tailings were used as backfill in underground mines or placed in low areas on the ground surface and confined by dams. Surface tailings could be left bare, covered with soil, or flooded. However, in recent years, regulatory requirements with respect to tailings have been made much more stringent.

Recent tailings management methods now include the chemical treatment of the tailings before they are discharged into the TMF; and, the containment structures that hold surface tailings have become more rigorously engineered for long-term stability. In some mines, tailings are returned underground for permanent storage. During an active operation, tailings are covered by water to reduce surface radioactivity and radon emission. As described in sections 1.3.1 and 1.4.1, ore treatment is often remote from the mine at a centralized facility and disposal of tailings is in engineered open pits that remain from earlier mining that took place at these sites.

On completion of the mining operation, a common practice is for the tailings to be covered with some two metres of clay and topsoil to reduce radiation levels to near those

normally experienced in the region of the orebody, and for a vegetation cover to be established.

Uranium mine and mill tailings constitute one of the three categories of radioactive waste. Tailings sites thus fall under the regulatory responsibility of the CNSC. Although the management of tailings during the period the mine is operating is a significant challenge, the long-term management of tailings for many years after the mine has shut down, as discussed in the following section, constitutes one of the greatest challenges in the planning and operation of a modern uranium mine. Of potential concern in the North is the predicted thawing of permafrost brought about by climate change. This may have an impact on the long-term stability of the structures used to impound the tailings and would clearly be given special consideration in their design and construction.

1.8 Reclamation and Decommissioning

After the ore at a mine has been exhausted, the site is reclaimed and the mine is decommissioned. Reclamation involves the removal of all buildings and structures at the site and the returning of the site to as near its original natural condition as practicable. The term "decommissioning" may also be used to describe the process taken following the permanent closure of the mining operation. A primary objective of decommissioning is to dispose of all hazardous materials in such a manner that no continued effluent treatment is required. Monitoring programs are required to demonstrate that this objective is being met.

The regulations under Nuclear Safety and Control Act contain requirements for decommissioning planning and financial assurances before a project receives an operating licence. (Matters relating to liability and financial security are discussed in section 4.7.4 of this paper.) During the operation, the plan is periodically reviewed and modified as necessary. When the decision is taken to shut the operation down permanently, detailed planning and environmental assessment commences. The environmental assessment may include a public hearing, at the discretion of the regulatory agencies. When the federal and other regulatory agencies are satisfied with this work, a decommissioning licence is issued and actual decommissioning commences.

During decommissioning, all the regulations for radiation protection, general safety and environmental protection continue to apply. These require such things as cost-benefit analysis to demonstrate that work is being done in a manner to control radiation exposures as low as reasonably achievable, economic and social factors being taken into account.

After completion of decommissioning, a period of monitoring follows to demonstrate that the site is performing as expected in the environmental assessment. When this has been demonstrated, permission is given for the operator to relinquish its licence(s) from the regulator(s) – referred to as “abandonment” in the CNSC regulations. Responsibility for

the site, including any long-term needs for monitoring or land use controls, then reverts to the Crown or other owner of the land. (A discussion paper to advance development of the provincial long-term institutional control framework was expected in Saskatchewan in 2005.)

It should be emphasized that uranium operations generally do not involve high enough radiation fields to cause any immediate threat to health and safety of workers or the public. The main concern is usually for reducing potential collective dose over long periods of time.

1.9 Monitoring

1.9.1 Monitoring Programs

Extensive monitoring programs are carried out both during the mining process and after the mine is decommissioned to ensure that radioactive material is not spread to the vegetation or into the air or water, and from these taken up by animals and eventually humans. These include:

- Compliance-based monitoring that demonstrates that regulatory conditions required by government agencies are met. This monitoring, done at the mine sites, involves air and water sampling to confirm that any emissions are within regulatory requirements.
- Environmental effects monitoring that ensures that the environment is not significantly adversely affected by mining and related activities. This monitoring of air, water, animals, fish and plants takes place on and off the mine sites.

1.9.2 Long-Term Monitoring of Tailings

In most instances, when a mine is closed and the site reclaimed, the TMF will be covered over or otherwise made stable. However, there may be situations in which the tailings will require monitoring for many years after the mine has closed, possibly even on a "perpetual' basis, that is, for as long as there is still a potential problem, which may extend for many, many years into the future.

For example, the 1997 report of the Federal-Provincial panel on the proposed Cigar Lake uranium mine in Saskatchewan said: "It is recommended that long-term monitoring be introduced to protect future generations from unacceptable impacts." The report went on to say, "Arrangements should be made to monitor this site in perpetuity, and resources retained to mitigate any undesirable impacts." The panel recommended that a fund be set up to finance this work and an authority be set up to oversee it.

We note that every mine would have its own unique circumstances and such long-term monitoring will not necessarily be required. We also point out that such long-term

monitoring would presumably be carried out by workers from the nearby community and would provide at least a modest source of income for many years.

1.10 McClean Lake Operation

The McClean Lake operation is one of the three currently producing uranium mines in Saskatchewan. The operation, which includes open pit mines and a mill, was one of the two uranium mining operations visited by NTI and the RIAs as well as other Nunavut groups in the fall of 2005.

Uranium mineralization was first discovered at the McClean Lake site in 1979, with additional orebodies discovered during the 1980's.[32] The project is operated by AREVA Resources Canada Inc., part of the AREVA Group of companies (AREVA). Ownership of McClean Lake Operation is AREVA (70%), Denison Mines (22.5%), and OURD Canada (7.5%). Uranium production started in 1999, with annual production of approximately 6 million pounds of U_3O_8. The mill has since been upgraded and the current licensed capacity of the operation is 12 million pounds U_3O_8 annually. As of December 2004, the remaining stockpiled and in-situ reserves were reported as 32.9 million pounds of U_3O_8 at an average grade of 1.7%.[33]

Open pit mining of the JEB orebody began in 1995. Once the ore was removed and stockpiled, the JEB pit was developed as the tailings management facility (TMF). Open pit mining of the five Sue ore bodies is in progress, leaving the McClean ore body for future underground mining. Open pit mining of the Sue ore bodies progresses as required to supply ore to the mill with the first (Sue C) completed in 2002, and the next (Sue A) planned to start in 2005. This will immediately be followed by Sue E, pending regulatory approvals.

Figure 7. Open pit mining at McClean Lake mine.

The McClean Lake Mill (JEB mill) has been designed both to efficiently produce a high quality uranium concentrate, and to provide a high level of protection for workers and the environment while processing high grade ores. The mill uses standard proven processes

[32] Some of the Information about McClean Lake was supplied by AREVA.
[33] http: //www.arevaresources.com/operation/mcclean/index.html

to leach uranium from the ore, and to recover the uranium product from the resulting uranium-bearing solution. The product is dried at high temperature and final concentrate packaged into drums for transport.

Figure 8. Mill at McClean Lake mine/mill operation.

The mill contains many special features to protect workers and the environment. Radiation shielding and containment of potential contaminants are extensively incorporated. The ventilation system is designed to maintain pressure differences. A positive pressure is maintained with fresh air supply to clean areas (for example, control rooms) and a lower pressure in potentially contaminated enclosures (for example the shielded cells for the leaching tanks), from where is air is exhausted. Five years of operating experience have confirmed that all regulatory requirements have been consistently achieved, with large margins between actual performance and minimum required performance.

The McClean Lake Tailings Management Facility (TMF) provides a state-of-the-art approach for protection of health, safety and environment. The TMF has been designed to provide environmental protection both over the operational period and for the long term. For example, tailings are transported from the mill to the TMF through a continuously monitored pipe-in-pipe containment system. Depositing the tailings in the TMF under water protects the operating staff from potential radiation and airborne emissions, and prevents freezing of the tailings during winter operation. Environmental protection is based on hydraulic containment of the TMF during operation and long-term safety after decommissioning without the need for any active system. Features of the preparation of tailings, such as converting arsenic (a potential contaminant present originally in the ore) to a stable form further increase environmental protection. The TMF is also designed for the decommissioning that will eventually take place, leaving an impervious, covered “plug” of tailings within the much more permeable surrounding sandstone bedrock. This will provide a passive means of protecting the environment from the release of contaminants over the long term.

Figure 9. Left – overview of McClean (JEB) mill with ore stockpiles to the left, JEB Tailings Management Facility (TMF) in the foreground and the camp to the right; Centre and right – JEB TMF with tailings covered by water.
