Working Paper FNU78

Abstract

The threat of an abrupt and extreme rise in sea level is widely discussed in the media, but little understood in practise, including the likely impacts of such a rise. This paper explores for the first time the global impacts of extreme sea-level rise, triggered by a hypothetical collapse of the West Antarctic Ice Sheet (WAIS). As the potential contributions remain uncertain, a wide range of scenarios are explored: WAIS contributions to sea-level rise of between 0.5m/century up to 5m/century. Together with other business-as-usual sea-level contributions, in the worst case this gives an approximately 6-m rise of global-mean sea level from 2030 to 2130. Global exposure to extreme sea-level rise is significant: roughly 400 million people (or about 8% of global population) are threatened by a 5-m rise in sea level, just based on 1995 data. The coastal module within the FUND model is tuned with global data on coastal zone characteristics concerning population, land areas and land use, and then used for impact analysis under the extreme sea-level rise scenarios. The model considers the interaction of (dry)land loss, wetland loss, protection costs and human displacement, assuming perfect adaptation based on cost-benefit analysis. Unlike earlier analyses, response costs are represented in a non-linear manner, including a sensitivity analysis based on response costs.

It is found that much of the world's coast would be abandoned given these extreme scenarios, although according to the global model, significant lengths of the world's coast are worth defending even in the most extreme case. Hence, this suggests that actual population displacement would be a small fraction of the potential population displacement. This result is consistent with the present distribution of coastal population, which is heavily concentrated in specific areas. Hence a partial defence can protect most of the world's coastal population.

1

However, protection costs rise substantially diverting large amounts of investment from other sectors, and large areas of (dry)land and coastal wetlands are still predicted to be lost. While some observations of response to abrupt relative sea-level rise due to subsidence support the global model results, detailed case studies of the WAIS collapse in the Netherlands, Thames Estuary and the Rhone delta suggest a greater potential for abandonment than shown by the global model. This probably reflects a range of issues, including: (1) economic criteria such as the cost-benefit ratio is not the only factor which drives response decisions, with wider perceptions of risk driving the actual response; (2) the inefficiencies of adaptation in the real world, including indecision and competition for limited resources; and (3) the possible loss of confidence under the scenario of abrupt climate change. Collectively, these results illustrate an area where there are potential limits to adaptation, even when economic analysis suggests that adaptation will occur. The significant impacts found in the global model together with the potential for greater impacts as found in the detailed case studies shows that the response to abrupt sea-level rise is worthy of further research, including exploring the differing impact results by scale.

Key words: Abrupt climate change, sea-level rise, coastal impacts, adaptation, adaptation limits.

1. Introduction

Low probability, high impact climate-induced events have been used in climate policy and climate policy advice to argue for stringent greenhouse gas emission reduction. Examples of such events include the shutdown of the thermohaline circulation, the release of methyl hydrates from the deep ocean, or the collapse of the West-Antarctic Ice Sheet (WAIS). In most cases, the "high impact" is known in physical terms, but human dimensions are essentially speculative. Taking the WAIS collapse example, it will impact coastal areas where average population densities are highest and there is a concentration of urban areas (Small and Nicholls, 2003), so there is clearly a high impact potential. Conventional wisdom often assumes universal coastal abandonment under such a scenario, but prior to the Atlantis Project, this has only been systematically investigated in two national-scale national assessments (Schneider and Chen, 1980; Rijkswaterstaat, 1986). In this paper, we attempt a first estimate of the global impacts of a WAIS collapse in an integrated analysis of dryland[1] loss, wetland loss, coastal protection, and human displacement. These results are then compared to the outcomes of the three detailed European case studies (Olsthoorn et al., 2005; Lonsdale et al., 2005; Poumadere et al., 2005).

Any global analysis is an ambitious goal, and we do not claim to have gone beyond a first, crude estimate of the order of magnitude of change. The goal is so ambitious because the conventional methods of climate change impact analysis breakdown under large changes such as the impact of a 5-m sea-level rise. A 1-m sea-level rise, the maximum scenario considered in the vast majority of studies, can be considered as a marginal change, not in the sense of not being important, but in the formal, mathematical sense of the word. That is, a 1-m sea-level rise would perturb the current situation, and the size of the perturbation can be studied with an essentially linear model. On the other hand, a 5-m rise of sea level would have impacts that extend beyond the coastal zone, and alter the coastal zone in a dramatic manner. For instance, the analysis of Olsthoorn et al. (2005) suggests that the harbour of Rotterdam (and by implication the harbours of Antwerp and Bremen) may be abandoned under a 5-m sea-level

---

[1] Henceforth dryland loss is simply referred to as land loss

rise, which would radically change transport patterns in the whole of Western Europe. In contrast, a 1-m sea-level rise would increase costs in Rotterdam Harbour, but would not fundamentally affect its operations, and its competitors are similarly affected.

In this paper, we approach this problem in two distinct ways. Firstly, we examine the basic data on exposure to sea-level rise. Whereas a 1-m sea-level rise has about twice the impact potential as a 0.5-m sea-level rise, a 5-m sea-level rise does not have 10 times the impact potential. Using a recent digital elevation model, we estimate population distribution up to 10 metres elevation. Secondly, we took an existing model of the costs of coastal protection and made it non-linear. This immediately affects the associated model of the level of coastal protection, which is now also non-linear. We do not pretend that these two changes solve all problems, but the work presented below is more than a simple extrapolation of previous work for smaller rises in sea level to a 5-m rise.

To our knowledge, this is the third paper analysing the impacts of a 5-m sea-level rise and the first to consider global impacts. The first paper (Schneider and Chen, 1980) is based on now outdated methods and observations and only considers the United States. The method used also only considers exposure based on elevation. The second paper (Rijkswaterstaat, 1986) is limited to the Netherlands; its methods are more advanced than those of Schneider and Chen (1980), and it concludes that the Netherlands could be maintained in the face of 5-m sea-level rise over 200 years (see Olsthoorn *et al.*, 2005). Note that there are numerous previous results for global impacts of sea-level rise up to a 1-m rise scenario (e.g., Hoozemans *et al.*, 1993; Fankhauser, 1994; Nicholls, 2004; Tol, 2004; Nicholls and Tol, 2005), and some national results for impacts up to a 2-m rise scenario (e.g., Titus *et al.*, 1991; Nicholls and Leatherman, 1995a).

The paper proceeds as follows. In Section 2, we briefly survey the literature on the West-Antarctic Ice Sheet and its possible collapse. In Section 3, we describe the potential exposure of land, population, GDP and land use to extreme sea-level rise scenarios. In Section 4, we present the impact model and its modifications for non-linear impacts under extreme sea-level rise. In Section 5, we discuss the impact results, while Section 6 discuss the overall results and concludes.

2.   Previous literature

The WAIS comprises about 10% by volume of the entire Antarctic ice sheet, and in volume is equivalent to a 5- to 6-m rise in sea level (Vaughan and Spouge, 2002; Oppenheimer and Alley, 2004). It is maintained by a balance of precipitation across the sheet, and seaward flow across the ice sheet, to the floating ice shelves. Here there is melting on the underside of the ice shelf, or iceberg calving at the periphery. Mercer (1978) caught the attention of policymakers when he speculated that human-induced global warming could cause the ice shelves of West Antarctica to disintegrate during the 21st Century, allowing the ice sheet to be catastrophically released into the ocean by a sliding mechanism (see also Oppenheimer, 1998). This would raise global-mean sea level by displacement alone, and there is no requirement for the ice to melt. Thus, the resulting rise could be much faster than for example the loss of the Greenland ice sheet, which would require melting of the ice to raise sea level, taking many hundreds or even thousands of years (Gregory *et al.*, 2004). (Note that the WAIS would also take a long time to melt, taking hundreds or thousands of years, even if the ice was floating). Recent observations of the break up of smaller ice shelves in Antarctica has maintained concern about WAIS collapse (Oppenheimer and Alley, 2004).

Having established this risk, there was widespread concern about the likelihood of extreme sea-level rise, and the maximum rate of rise that might be possible (see Kasperson et al., 2005

for a more detailed review). There are widely divergent views ranging from considering the mechanism to be almost impossible, to expectations that WAIS collapse may begin in the 21st Century, with WAIS collapse being strongly equated to 'dangerous climate change' (Smith et al., 2001; Oppenheimer and Alley, 2004). Vaughan and Spouge (2002) recently conducted a formal risk assessment of the WAIS collapse, including using a Delphi technique and a panel of experts to explore these uncertainties and estimate the resulting risk. The complexity of the collapse mechanism is captured in their Figure 2, illustrating the range of processes of interest when trying to understand WAIS collapse. They concluded that there is a 5% probability of the WAIS causing a sea-level rise of at least 10 mm/yr (or 1 m/century) within 200 years. In terms of total rise due to the WAIS contribution, they estimated a 5% probability of a rise greater than about 0.5 m by 2100 (averaging 0.5 m/century), about 2.3 m by 2500 (averaging 0.46 m/century), and about 3.2 m rise by 4000. Hence, none of these estimates equate to a total WAIS collapse. Kasperson *et al.* (2005) also emphasizes the uncertainties and disagreements between experts that the Vaughan and Spouge analysis reveals.

The goal of the Atlantis Project was to examine an extreme scenario, and especially to understand the societal response to such an extreme change. Given the current status of scientific knowledge, including discussions with relevant glaciologists, the total collapse of the WAIS in relatively short time scales of 100 to 200 years cannot presently be stated as impossible. Given the limited resources available for the three detailed case studies, it was decided that we would learn most about the response by considering the most extreme scenario – a 5-m rise in 100 years due to the WAIS collapse. The scenario was kept deliberately simple and was applied linearly from 2030 for all the three case studies discussed below. In 2130, the rise ceases, as abruptly as it began. Even if this extreme Atlantis scenario is demonstrated to be totally impossible, the intellectual exercise of thinking through an extreme scenario to impacts and especially responses has been very valuable and informative, both for coastal impacts and more generally to understanding extreme climate change (Tol *et al.*, 2005). This might be an important lesson to others studying extreme climate change.

Unlike the detailed case studies in the rest of the project, the global analysis was able to explore a wider range of scenarios of WAIS contribution to sea-level rise, ranging from a 0.5 m/century up to a 5 m/century scenario, with a maximum contribution of 5 metres in all cases.

3. Exposure analysis

3.1 Data sources

The exposure analysis was based on a series of global datasets on population (two data sets), elevation, tidal range and administrative unit boundaries. These data sources are now discussed in turn.

Population data

The Gridded Population of the World, version 3 (GPW3) (CIESIN and CIAT, 2004) and Landscan (2003) (see also Dobson et al., 2000) were compared in the analysis, as there are considerable uncertainties in such data (e.g., Small and Nicholls, 2003). The LandScan dataset is a worldwide population database compiled on a 30×30 arcseconds latitude/longitude grid (about 1 km at the equator). Census counts (at sub-national level) were apportioned to each grid cell based on likelihood coefficients derived from a series of variables such as proximity to roads, slope, land cover, night time lights, and other data.

The GPW3 is the latest update of the GPW dataset: earlier versions have been extensively employed in a range of global population studies (e.g., Cohen *et al.*, 1997; Small and Nicholls, 2003). GPW adopts a simple population distribution algorithm gridded at the same

scale as Landscan, but putting more emphasis on the collection of the input data rather than modelling distributions (Nelson and Balk, 2003).

Elevation data

The elevation dataset that was employed is the SRTM Enhanced Global Map developed by ISciences (2003). The dataset has a resolution of 30 arc seconds (around 1km at the equator) and is based on data acquired from the Shuttle Radar Topography Mission (SRTM), which cover 80% of the earth's land surface. The SRTM data were supplemented with GTOPO30 elevation data for land areas that are covered in the SRTM30 dataset and also with ocean bathymetry data from ETOPO2.

Tidal range data

The tidal range dataset is a 1-degree resolution global dataset compiled according to the small-scale map of Davies (1980) containing a global overview of tidal range classes. The data used is derived from the LOICZ typology dataset (Maxwell and Buddemeier, 2003). Tidal range is presented as five classes, which were interpreted as average tidal range values and hence high water (tidal range/2).

Administrative unit boundaries

The GIS dataset of 1095 first-level subnational administrative boundaries that is included in the Digital Chart of the World (DCW) was employed in the present study (ESRI, 2002; Deichmann *et al.*, 2001). The DCW has been partially employed for the generation of the GPW3, which ensures consistency in our analysis.

Land use data

Land use was derived from a dataset that was developed by the IMAGE Team (2002). This dataset contains the global distribution of 19 principal land use types at 0.5°×0.5° resolution.

3.2   Data processing and analysis

Data processing was performed within a Geographic Information System (GIS), which provided the environment for the storage, the spatial analysis and the cartographic display of the geo-referenced datasets. Zonal statistical functions and data overlays were employed within the context of the spatial analysis that was performed in a series of steps. This included defining the population and land use by elevation up to 10-m above mean sea level. Then potential impacts defined relative to high water were considered. In the first step average tidal range values were estimated for all coastal administrative units. Then, based on these values and using the elevation dataset, land loss as a function of sea-level rise was calculated for each administrative unit and for two scenarios of sea-level rise: a 1-m and 5-m rise scenario, respectively. In this step, low-lying inland areas and water bodies were masked out. In the final step, resident coastal population counts for the areas lost were estimated using the GPW3 and Landscan datasets.

3.3   Results

Figure 1 shows key aspects of the global exposure to sea-level rise as a simple function of elevation above mean sea level. This includes the land area, the population, and their total income (measured at market exchange rates (MER) as well as at purchasing power parity (PPP)). Given the uncertainties in these global datasets, it is important not to over-interpret the results, and they should only be considered indicative (Small and Nicholls, 2003). The distributions are broadly linear up to a 10-m rise, with the exception of land area which increases more rapidly from 0-m to 1-m elevation, probably reflecting coastal wetlands and areas of land claim which both tend to be concentrated near mean sea level. The GPW3 and Landscan data are remarkably similar – Landscan estimates a larger population below 10-m elevation. (However, if we had used GPW2, the exposure would have been estimated as much higher.) Economic exposure is less when measured in MER than in PPP, indicating that a substantial part of the exposure is in developing countries.

Figure 2 shows the exposed land area again, but this time split up by land use. The exposed area consists mostly of agricultural land, boreal forest, and tundra. Residential areas only make a small contribution to the exposed area. Note that given the coarse resolution of the IMAGE data, these results are again indicative. Based on more detailed data, 20 out of 30 of the world's biggest cities are threatened and there is a concentration of smaller cities in vulnerable locations (Small and Nicholls, 2003).

Table 1 shows the impact given a 1-m and 5-m sea-level rise on area, population and total income assuming no coastal protection. These impacts are based on change relative to high water and hence are larger than those in Figure 1. It is assumed (reasonably) that all assets and population in this area are lost or forced to move. There would be additional potential impacts above high water due to various flood mechanisms, but these are considered minor compared to the impacts below high water and are not considered. The data suggests that area is less than linear, GDP slightly less than linear, and population more than linear as a function of sea-level rise.

4.   The impact model

The impact model considers impacts taking account of coastal protection, and uses version 2.8n of the *Climate Framework for Uncertainty, Negotiation and Distribution (FUND)*. Version 2.8n is different in many ways from previous versions. However, in this paper, only coastal impacts are considered as described in Tol (2002a, 2002b). The essential features are outlined below. Version 2.8n differs from version 2.8 (Link and Tol, 2004) in that version 2.8n runs resolves 207 countries; while version 2.8 has only 16 aggregated regions.

Essentially, *FUND*2.8n consists of a set of exogenous scenarios on which impacts are calculated. The model runs from 1995 to 2100 in time steps of five years. Population and economic growth follow the FUND scenario, which is close to the IS92a scenario (Leggett et al., 1992). Carbon dioxide concentrations, global mean temperature and sea-level rise are calculated with the FUND2.8 model (Link and Tol, 2004).

In this paper, the following impacts of sea-level rise are considered: (1) land loss, (2) wetland loss, (3) protection costs, and (4) forced migration, all assuming perfect adaptation based on cost-benefit analysis. These impacts interact with one another. For example, if land is fully protected, no land will be lost, but the associated costs of protection will be maximised, and any adjacent wetlands may experience greater losses. The total impact of sea-level rise depends on the adaptive policy chosen, and hence so does the estimated damage. For instance, Hoozemans *et al.* (1993) uses the *ad hoc* rule that all land with a population density above 10 people/km^2 will be protected, while Fankhauser (1994, 1995) and Yohe *et al.* (1995, 1996)

employ models which choose the economically optimal level of protection. The resulting difference in estimated impacts can be substantial.

The coastal length of all countries in the world was taken from the Global Vulnerability Assessment (GVA) (Hoozemans *et al.*, 1993). Other sources, such as the World Coast 1993 Conference (Bijlsma *et al.*, 1994), Nicholls and Leatherman (1995a, 1995b) and Fankhauser (1995), use (occasionally widely) different estimates of the length of the coast of particular countries. However, the length of a coast depends on the measurement procedure. The GVA is based on an internally consistent, globally comprehensive data-set, and is used here.

Wetland losses for a 1-m sea-level rise were taken from the GVA and, where available, replaced with results from country studies as reported by Bijlsma *et al.* (1996) plus Nicholls and Leatherman (1995a; 1995b). The GVA reports wetland losses both with and without coastal protection; the country-specific ratio between the two was used to derive wetland losses with protection according to Bijlsma *et al.* (1996). Without coastal protection, following the GVA, wetland loss is assumed to be linear in sea-level rise. While the resulting wetland model is simple and based on incomplete data, it is well understood and hence used in this exploratory analysis.

Land losses are not reported in the GVA, but they are provided by Bijlsma *et al.* (1996) for 18 countries. The GVA reports people-at-risk, which is the number of people living in the one-in-1000-year flood plain, weighted by the probability of flooding. Combining this parameter with the GVA's coastal population densities, allows area-at-risk to be estimated. The exponential of the geometric mean of the ratio between area-at-risk and land loss derived from the data in Bijlsma *et al.* (1996) was used as a correction factor to derive land loss for all other countries. In the GVA, without protection, land loss is assumed to be linear in sea-level rise. Here, we use a power function, $D=\alpha S^{\beta}$; α is such that the impacts are as in the GVA for $S=1$; β is estimated, for each country individually, from the data presented in Section 3. On average, $\beta=0.39$, but it ranges from $\beta=0.00$ in Monaco and Nauru, where there is little land between 1 and 5 metres, to $\beta=1.72$ in the Lebanon, where there is little land below 1 metre.

The monetary value of the loss of one square kilometre of land was on average \$4 million in OECD countries in 1990 (cf. Fankhauser, 1994). Land value is assumed to be proportional to GDP per square kilometre. Wetland losses were valued at \$2 million per square kilometre on average in the OECD in 1990 (cf. Fankhauser, 1994). The wetland value is assumed to have logistic relation to per capita income.

Land loss is assumed to lead to forced migration, which is a major concern under scenarios of WAIS collapse. Following Tol (1995), forced migration equals area lost times population density.

Coastal protection *against sea-level rise* is based on cost-benefit analysis, including the value of additional wetland lost due to the construction of dikes and subsequent coastal squeeze. The level of protection is derived by Fankhauser (1994):

$$L = \min\left\{0,1 - \frac{1}{2}\left(\frac{PC+WL}{DL}\right)\right\} \tag{1}$$

L is the fraction of the coastline to be protected. PC is the net present value of the protection if the whole coast is protected. The GVA reports average costs per year over the 21st century. PC is calculated assuming annual costs to be constant. This is based on the following three assumptions:

- the coastal protection decision makers *anticipate* a linear sea-level rise and linear land loss, even though these are not linear in actuality; if the anticipation were based on a

non-linear model, Equation (1) could not be written explicitly as a function, but would become the solution to a numerical optimisation problem.

- coastal protection comprises large infrastructural works which have a life of decades.

- considered costs are direct investments only, and the relevant technologies are mature.

Throughout the analysis, a pure rate of time preference, ρ, of 1% per year is used. The actual discount rate lies thus 1% above the growth rate of the economy, g. The net present costs of protection PC thus equal

$$PC = \sum_{t=1}^{\infty} \left(\frac{1}{1+\rho+g} \right)^t PC_a = \frac{1+\rho+g}{\rho+g} PC_a \tag{2}$$

where PC_a is the average annual costs of protection. The average annual costs are taken from the GVA. Again, the GVA assumes linearity. Because protection costs are at the heart of Equation (1), we replace this with a bilinear equation: If sea-level rise is less than 1 cm per year, protection costs are as the GVA; if not, they are 10 times as high.

WL is the net present value of wetlands loss due to full coastal protection. Land values are assumed constant, reflecting current preferences about the value of non-marketed services and goods. The amount of wetland loss is assumed to increase linearly over time. The net present costs of wetland loss WL follow from

$$WL = \sum_{t=0}^{\infty} t \left(\frac{1}{1+\rho+g} \right)^t WL_0 = \frac{1+\rho+g}{(\rho+g)^2} WL_0 \tag{3}$$

where WL_0 denotes the value of wetland loss in the first year.

DL denotes the net present value of the land loss if no protection takes place. Land values are assumed to rise at the same pace as the economy grows. The amount of land loss is assumed to increase linearly over time. The net present costs of land loss DL are

$$DL = \sum_{t=0}^{\infty} t \left(\frac{1}{1+\rho+g} \right)^t DL_0 = \frac{(1+g)(1+\rho+g)}{\rho^2} DL_0 \tag{4}$$

where DL_0 is the value of land loss in the first year.

The population and per capita income scenarios used are the FUND scenarios as shown up to 2300 in Table 2 (Link and Tol, 2004). These projections are for 16 world regions. Population change and per capita growth were assumed to be uniform for all countries within a region.

Using the population and economic scenarios, as well as the corresponding scenarios on technological progress, the full *FUND* model, version 2.8,[2] was used to generate scenarios of climate change and sea-level rise. CO_2 concentrations rise to 870 ppm by 2100, the global mean temperature is 3.5ºC above pre-industrial levels, and the global-mean sea level rises by 66 cm above 1990 levels.

For the WAIS collapse, we assume a wide range of scenarios ranging upwards from an additional contribution of 0.5 m/century up to the most extreme scenario of an additional sea-level rise of 5 metres between 2030 and 2130. For the other scenarios, we do not vary the start date for the WAIS collapse, but move the end date of the 5-m rise to 2230, 2230, 2330, 2430, 2530 and 3030, respectively. For comparative purposes, the IS92a scenario is also shown. Figure 3 shows the assumed scenarios of global-mean sea-level rise, allowing for both the WAIS and other sea-level contributions. While the probability of these events remains poorly

---

[2] That is, the version with 16 regions rather than 207 countries.

defined, the additional contribution of 0.5 m/century has a roughly 5% chance during the 21st Century according to Vaughan and Spouge (2002), and the larger rises are less likely.

In all cases, calculations deliberately proceed beyond the arbitrary time limit of 2100 to the year 2300, so that we can see the complete response, at least for some of the more extreme scenarios.

5.   Impact results

Figure 4 shows the fraction of the global coast that is protected for each scenario of sea-level rise. As soon as sea-level rise accelerates in 2030, the length of the world's coast that is protected declines from about 85% to about 50%, reflecting that protection becomes too expensive in many areas. The threshold of sea-level rise to trigger higher protection costs is exceeded at the same time for all the WAIS collapse scenarios, except for the slowest scenario in which the collapse takes 1,000 years. As soon as the WAIS collapse ceases, the rate of sea-level rise slows dramatically, and the length of coastal that is economic to protect returns to the fraction that it was before the WAIS collapse. However, this does not imply that the lost land would be reclaimed; rather, the new inland coastal position would be protected. In the slowest WAIS collapse scenario, the rate of sea-level rise does not immediately rise above 1 cm/yr, and then falls below the same threshold shortly after 2200. Given the assumptions on protection costs used in this analysis, this strongly influences the predicted protection response.

Figure 5 shows the global costs of coastal protection as a function of time. Despite the drop in length of coast that is protected (cf. Figure 4), the overall protection costs rise dramatically (by 30 times) in the largest scenario, and increase significantly even in the scenarios where the WAIS collapse takes 500 or 1,000 years. Thus, while the model suggests that it is beneficial to protect many coastal areas, this will be at the expense of other investment. In the slowest WAIS collapse scenario, the slower rate of sea-level rise influences the overall cost of defences, for the same reasons as outlined above.

Figure 6 shows the model estimates of cumulative land loss. Because sea-level rise is much faster, and hence protection levels fall, land losses are much higher with a WAIS collapse than without this change. If it takes 1,000 years for the WAIS to collapse, land loss increases threefold; if it takes 100 years, the increase is eightfold; both relative to the losses without WAIS collapse. Although *potential* land loss itself is less than linear as a function of sea-level rise (cf. Figure 1), when the effects are combined with coastal protection, *actual* land loss is more than linear.

Note that the numbers in Figure 6 are much lower than those in Figures 1-2 and Table 1. There are two reasons. Firstly, the numbers in Figure 6 include *additional* coastal protection as a response to sea level rise, whereas the numbers in Figures 1-2 and Table 1 do not. Secondly, and more importantly, the numbers in Figure 6 also include *current* coastal protection as estimated in the GVA by Hoozemans *et al.* (1993), whereas the numbers in Figures 1-2 and Table 1 do not. These differences stress the importance of considering relative rather than absolute results.

Figure 7 shows forced displacement of people. Without a WAIS collapse, forced displacement starts at around 75,000 people per year, but rapidly falls to some 5,000 people in 2050 as defences standards progressively improve. Note the disproportionate reaction of forced migration to increased protection levels (cf. Figure 4). With a WAIS collapse, forced migration soars. With a WAIS collapse in a 100 years, the number of forced migrants peaks at around 350,000 a year, and stays at that level for a decade. The model suggests that about 15 million people in total are displaced by the most extreme collapse scenario (2030 to 2130).

This is a significant impact and such population displacement would have major economic and other consequences. However, the numbers displaced are much smaller than the exposed population (Figure 1), only being 2% to 3% of the total, showing that the model predicts that most of the coastal population is protected.

Figure 8 shows the model estimates of coastal wetland area over time. Without a WAIS collapse, wetland area falls because of a combination of sea-level rise and coastal protection (which removes areas for wetlands to migrate inland which is termed coastal squeeze). The annual rate of loss diminishes with time because a large number of wetlands have disappeared completely. With a WAIS collapse, coastal wetland area declines even more rapidly, showing that the impact of the additional sea-level rise outweighs the benefits of reduced coastal protection. In the scenario without WAIS collapse, about 1/3 of global wetlands disappears; with the most rapid WAIS collapse in 100 years causes about 2/3 of global wetlands disappears. Given that wetland loss is a non-linear process (Nicholls, 2004), losses for the higher rates of change may be underestimated.

6.   Sensitivity analysis

These results are sensitive to our assumptions and the scenarios that we have used, as shown in earlier analyses (Tol, 2002a, 2002b; 2004). If emissions were higher, so would impacts. If people were richer, coastal protection would be more extensive and effective, and impacts would be lower. If wetlands were more sensitive, impacts would be higher. If coastal protection were more expensive, protection would be lower, and impacts higher. Here we present two additional sensitivity analyses that illustrate the features of the response to the WAIS collapse.

The cost of coastal protection is a crucial parameter in the analysis, because it essentially determines the extent of protection[3]. Protection costs are specified as a bilinear model, where the costs are 10 times higher if sea level rises faster than 1 cm per year; we refer to this as the *cost increase factor*. In Figures 9 and 10, we show the results for cost increase factors of 5, 20 and 100. (Based on dike costs being quadratic, in round terms cost factors of 1, 5, 10 and 20 correspond to dike heights of 1-m, 2-m, 3-m and 4.5-m, respectively, with the 1-m cost derived directly from the GVA). We also show the case of a cost increase factor of unity, which is the original model, unadjusted for extreme sea-level rise scenarios. Figure 9 shows the fraction of coast protected for the scenarios in which the WAIS collapses in 100 and in 500 years. As one would expect, higher costs leads to less protection. However, the amount of protection falls much more between a cost increase factor of 5 and 10, than between a cost increase factor of 10 and 20, and 20 and 100. Hence the model suggests that even if the cost increase factor was 100[4], roughly 35% of the world's coast would still be worth protecting. In effect, the analysis with the FUND model suggests that some coasts are so valuable that they will be protected regardless of the rise in sea level over the range that is physically plausible. . Figure 10 shows the corresponding land loss. Here, the response of land loss is also less than linear in the cost increase factor, but this is less pronounced than for the protection level.

The other adjustment made to the model in order to analyse extreme sea-level rise, is the non-linear land loss function derived from the exposure analysis. Figures 9 and 10 also show what would have been the results, had we not made this adjustment and used a linear function

---

[3] Actually, what matters is the cost of protection relative to the value of land. We keep the latter constant and vary the former.
[4] This is possible in some locations if we assume the worst-case sea-level rise scenario and the corresponding increase in wave heights as they break closer and closer to the shoreline (Townend, 1994; Townend and Burgess, 2004).

instead. Coastal protection is hardly affected, as the decision makers assumed linearity anyway, regardless of the "actual" world (cf. Figure 9). However, estimates of land loss would have been considerably higher, and the original model would have overestimated the impacts of a WAIS collapse.

Above, we discuss the differences between Figures 1-2 and Table 1, on the one hand, and Figure 6 on the other. We argue that the exposure analysis (Figure 1-3) may overestimate the impact of a 1-m rise (Figure 6) as the exposure analysis ignored current coastal protection. However, for a 5-m rise, current coastal protection is largely irrelevant. This suggests that the non-linearity of the response of land loss (without additional protection) should not be based on the exposure analysis for 1 and 5 metres, but rather on the impact analysis (without additional protection) for 1 metre and the exposure analysis for 5 metres. As a result, the model would become more non-linear. Figures 9 and 10 show the results if we make this assumption. Coastal protection is hardly affected (Figure 9), for the same reason as above. However, the estimates of land loss would be considerably higher, by a factor of about 20 (or 40) for a 5-m sea level rise in 2530 (or 2130).

7.　　Discussion and conclusion

This analysis suggests that a significant acceleration of sea-level rise due to a WAIS collapse (or any other cause) could have a profound effect on the impacts of sea-level rise. In terms of a cost-benefit analysis and perfect adaptation, it suggests that it would be appropriate to abandon large lengths of the world's coasts, although about 30% to 50% of the world's coasts could still be optimally protected under such a cost-benefit analysis. The optimum amount of protection depends on the protection cost, and while optimum in a cost-benefit sense, the increased investment in protection would divert significant resources away from other investment needs.

Given the extent of protection that is predicted by the model, so the number of people displaced is also much lower than widely assumed. Up to 15 million people are estimated to be displaced from 2030 to 2130, although this number could increase with a higher cost increase factor. Population distribution in the near-coastal zone is known to be strongly non-uniform (Small and Nicholls, 2003), and hence, relatively small lengths of defences can protect a significant fraction of the coastal population. Here 50% protection protects >95% of the coastal population. The length of protection required to achieve this goal might well fall further if the analysis was performed at sub-national scale as demonstrated for East Anglia, England by Turner *et al.* (1995), and this should be investigated.

On the other hand, the amount of protection suggested by the global model is surprising, as there is a widespread view that any large rise in sea level is beyond our capacity to adapt and a global retreat will result. Independent support for the model results presented here can be found from subsiding coastal cities during the 20th Century such as Tokyo which subsided up to 5-m due to groundwater withdrawal (Nicholls, 1995). Nonetheless, the response to such large relative sea-level rise was always to protect, and coastal cities such as Tianjin, Shanghai, Tokyo, Osaka and Bangkok presently have large areas below normal tides which are dependent on flood defences and pumped drainage to avoid flooding. In contrast, the global model appears to conflict with the three detailed case studies of WAIS collapse, which all suggest a greater tendency towards coastal abandonment and retreat than the global model even in major urban areas such as London and the Netherlands (see Table 3). This difference partly reflects factors that are not considered in the global model, such as an overall loss of confidence due to the rapid sea-level rise, which in turn, may trigger a cycle of decline. In the Netherlands, response costs where estimated at 3% to 4% of GDP, which was considered

prohibitive in terms of other demands on the national economy. It was also observed in the Thames Estuary case study that paralysis which might well delay an adaptation response too long for it to be effective, leaving retreat as the only viable option. Again this process is not included in the global model which assumes perfect adaptation if it has an appropriate cost-benefit ratio.

Barnett and Adger (2003) discussed the role of social-ecological thresholds in triggering island abandonment, and an empirical analysis of an historic island abandonment in the Chesapeake Bay by Gibbons and Nicholls (2005) supports the validity of this concept. The different results for the global model and the case studies suggests that the notion of social-ecological thresholds may have widespread value when thinking about abrupt climate change. These differences also raise questions about the different controls on limits to adaptation, which is important information to climate policy.

Therefore, collectively the Atlantis project results show that a WAIS collapse would have profound effects on the world's coasts, but it remains uncertain to what extent we would be able to respond.

Even with protection as widespread as suggested by a cost-benefit analysis, the impacts of a even a slow WAIS collapse would be substantial. Protection costs would increase by a factor of 10 or more; land loss and forced migration would go up by a factor of 5 or more; wetland loss would double or more compared to a scenario without a WAIS collapse. Faster WAIS collapse would exacerbate all these impacts.

These results also illustrate that the impacts of sea-level rise are non-linear, even in a simple coupled model as used here. Potential land loss is less than linear in sea-level rise. Actual land loss, in contrast, is more than linear, as coastal protection cannot keep up with higher rates of sea-level rise. For even higher sea-level rise, the response becomes again less than linear, as more and more of the most susceptible areas are abandoned.

The research presented here is only a first exploration of the global impacts of extreme sea-level rise, using a simple coupled model with a number of limiting assumptions and a comparison with detailed case studies. Our ability to protect is fundamental to the actual impacts of WAIS collapse and this remains uncertain as discussed above – this raises technical, economic and socio-political questions. Even in the most optimistic situation with widespread protection being possible, the overall consequences are sufficiently alarming to justify a range of further research (see also Kasperson *et al.*, 2005). In physical terms, scenarios or even probabilities of WAIS collapse linked to different climate change scenarios are desirable, albeit extremely difficult to develop (Nicholls and Lowe, 2004). In impact terms, the analysis discussed here could be refined with more detail in terms of coastal data, impact models and representation of adaptation. Such a study could yield important insights into the limits to adaptation, which are suggested here, including the full range of controls that influence these limits. This information is fundamental to understand how society may, or may not, be able to respond to abrupt climate change.

Table 3. Summary of the response of three detailed case studies to the Atlantis sea-level rise scenario (5-m rise from 2030 to 2130).

Case Study	Impacts	Response	Source
Netherlands	> 10 million people threatened together with one of the world's largest economies	Abandon the northwest and southwest of the Netherlands, but possibly protect the Ranstad (Amsterdam to Rotterdam area). Likelihood of intense political conflict and very large response costs in proportion to GDP	Olsthoorn et al. (2005)
Thames estuary	2 million people threatened with a rapidly increasing flood risk without a response, even allowing for expected upgrades. Also much of London's financial sector including Canary Wharf.	Indecision may lead to forced abandonment, but there are adaptation options – especially a new downstream barrier	Lonsdale et al. (2005) Dawson et al. (2005)
Rhone delta	Compared to the other case study sites, human impacts are minimal, but significant natural values are threatended.	After an initial 'wait and see', abandon the delta.	Poumadere et al., (2005)
