Measurement of Anti-Deuteron Photoproduction and a Search for Heavy Stable Charged Particles at HERA

H1 Collaboration

Abstract

The cross section for anti-deuteron photoproduction is measured at HERA at a mean centre-of-mass energy of $W_{\gamma p} = 200$ GeV in the range $0.2 < p_T/M < 0.7$ and $|y| < 0.4$, where M, p_T and y are the mass, transverse momentum and rapidity in the laboratory frame of the anti-deuteron, respectively. The numbers of anti-deuterons per event are found to be similar in photoproduction to those in central proton-proton collisions at the CERN ISR but much lower than those in central Au-Au collisions at RHIC. The coalescence parameter B_2, which characterizes the likelihood of anti-deuteron production, is measured in photoproduction to be $0.010 \pm 0.002 \pm 0.001$, which is much higher than in Au-Au collisions at a similar nucleon-nucleon centre-of-mass energy. No significant production of particles heavier than deuterons is observed and upper limits are set on the photoproduction cross sections for such particles.

1 Introduction

This paper describes a measurement of the rate of production of anti-deuterons in photon-proton collisions at HERA performed by the H1 Collaboration. The measurement is of particular interest in the context of recent studies of heavy ion collisions [1]. In these collisions, the deuteron and anti-deuteron production rate is thought to depend on the dimensions of the collision "fireball" at the stage at which the hadrons decouple [2], i.e. when final state interactions become unimportant. This is the so-called "thermal freeze-out" region.

Further, a search is performed for the photoproduction of unknown charged stable heavy particles in the highest energy electron-proton collisions currently accessible in the laboratory. The discovery of such particles would be an indication for physics beyond the Standard Model.

The production of nuclei in particle collisions can be described in terms of the coalescence model. In this model [3], the cross section, σ_A, for the formation of an object with A nucleons with total energy E_A and momentum P, is related to that for the production of free nucleons in the same reaction, σ_N, with energy E_N and momentum $p = P/A$, by

$$\frac{1}{\sigma}\frac{E_A \mathrm{d}^3\sigma_\mathrm{A}}{\mathrm{d}^3\mathrm{P}} = B_A \left(\frac{1}{\sigma}\frac{E_N \mathrm{d}^3\sigma_\mathrm{N}}{\mathrm{d}^3\mathrm{p}}\right)^A , \tag{1}$$

where B_A is the coalescence parameter, which is inversely proportional to the source volume in heavy ion collisions [2], and σ is the total interaction cross section of the colliding particles.

For the measurements described here, the particles are identified through a combination of their specific ionisation energy loss, $\mathrm{d}E/\mathrm{d}x$, and their momenta. The numbers of anti-deuterons are measured in the laboratory frame in the rapidity region $|y| < 0.4$ which corresponds to a centre-of-mass rapidity of between 1.6 and 2.4 units[1]. In this range, the multiplicity distributions are on the central plateau [4] and so comparisons can reasonably be made with the measured numbers of anti-deuterons per event in central proton-proton collisions [5, 6]. Both are contrasted with data from heavy ion collisions [7, 8]. These comparisons are restricted to central collisions at a centre-of-mass energy greater than $50\,\mathrm{GeV}$, i.e. well above the threshold for anti-deuteron production. There have been several other measurements of anti-deuteron production in proton-proton (pp) [9], proton-nucleus (pA) [10], nucleus-nucleus (AA) [8] and electron-positron [11] collisions. These measurements are either for non-central production or are at a centre-of-mass energy below $50\,\mathrm{GeV}$.

2 Experimental Procedure

2.1 The H1 Detector

Collisions of $27.6\,\mathrm{GeV}$ positrons with $820\,\mathrm{GeV}$ protons at HERA are detected in the H1 detector, which is described in detail elsewhere [12]. The components of the detector important in

[1] The rapidity and pseudorapidity are defined by $y = 0.5\,\ln[(E+p_z)/(E-p_z)]$ and $\eta = -\ln(\tan\theta/2)$ for a particle with total energy E, z component of momentum p_z and polar angle θ. The $+z$-axis (forward direction) is taken to be along the proton beam direction.

this analysis are the small angle positron tagger, the central tracker, the backward Spaghetti-type calorimeter (SpaCal) and the liquid argon (LAr) calorimeter.

The positron tagger, located at $33\,\mathrm{m}$ from the interaction point in the outgoing positron beam direction, is used to trigger on photoproduction events and to measure the energy of the scattered positron, from which the total photon-proton centre-of-mass energy, $W_{\gamma p}$, is deduced. The central track detector, surrounding the 9 cm diameter aluminium beam pipe of thickness 1.7 mm, consists of concentric central jet drift chambers (CJCs) with inner (CJC1) and outer (CJC2) chambers and two additional drift chambers which measure the z coordinates of tracks. The pseudorapidity range covered by the central track detector is $|\eta| < 1.5$. The CJC has 56 sensitive wire layers: 24 in CJC1 covering radii from 20.3 cm to 45.1 cm and 32 in CJC2 covering radii from 53.0 cm to 84.4 cm. The detector is placed inside a uniform magnetic field of 1.15 T, allowing measurements of the track transverse momentum to be made with a resolution of $\sigma_{p_T}/p_T \approx 0.009 \cdot p_T[\,\mathrm{GeV}] \oplus 0.015$. The specific energy loss, $\mathrm{d}E/\mathrm{d}x$, of the charged particles is also measured in this detector with a resolution $\sigma(\mathrm{d}E/\mathrm{d}x)/(\mathrm{d}E/\mathrm{d}x)$ of 7.5% for 56 hits on a minimum ionising track. The LAr calorimeter covers the angular range $4^\circ < \theta < 154^\circ$ with the forward region defined to be $4^\circ < \theta < 25^\circ$. The SpaCal calorimeter covers the backward region, i.e. the angular range $153^\circ < \theta < 177.8^\circ$. The luminosity is measured via the well understood Bethe-Heitler process, $ep \to ep\gamma$, using a photon detector at 0° to the positron beam direction.

2.2 Trigger Conditions, Event and Track Selection

The measurements presented here are based on H1 data taken with minimally biased triggers in 1996 and correspond to an integrated luminosity of 5.53 ± 0.11 pb^{-1}. Photoproduction events are triggered by requiring the presence of tracks in the CJC and of a scattered positron in the positron tagger, which ensures that the photon virtuality $Q^2 < 10^{-2}$ GeV^2. The following selection criteria are applied in order to reduce the background contamination and to ensure good reconstruction of the event kinematics. The selected events are required to lie within the interval $165 < W_{\gamma p} < 252\,\mathrm{GeV}$ (average $\langle W_{\gamma p} \rangle = 200\,\mathrm{GeV}$). In this range the total acceptance of the positron tagger for photoproduction events is 0.46 ± 0.02. In addition, five or more tracks are required to be reconstructed in the CJC. These tracks must point to a common vertex with z coordinate within ± 30 cm of the nominal interaction point.

Candidate tracks for particle identification are selected in the range $|\eta| < 1$ so that they are well contained within the CJC. Here the track reconstruction and particle identification efficiencies are high. Two track selection schemes are used: the "hard" and "soft" selections. The minimum ionising particle (MIP) background is larger in the soft selection scheme than in the hard selection scheme. The hard selection is used to search for rare heavy particles, when it is necessary to minimise this background and to have optimum $\mathrm{d}E/\mathrm{d}x$ resolution. The soft selection is used only for copiously produced particles such as protons and anti-protons.

In the soft selection, the tracks are required to have at least 10 hits and to have a start point at radius < 30 cm from the beam line and an end point at radius > 37.5 cm. The total measured radial track length is required to be more than 10 cm and the specific energy loss to be more

than twice that of a MIP, i.e. $\log_{10} \mathrm{d}E/\mathrm{d}x > 0.3$.[2] These criteria are loose enough to ensure that the combined track reconstruction and particle identification efficiency is high (measured to be $98.8 \pm 0.2\%$). In the hard selection, tracks are required to pass through both CJC1 and CJC2. The number of hits in CJC1 is required to be at least 20 with a minimum of 40 hits in both chambers. The total measured radial track length must be greater than 35 cm. In addition, the selected tracks must have a minimum of 75% of the total number of possible hits and a specific energy loss of more than 2.5 times that of a MIP, i.e. $\log_{10}(\mathrm{d}E/\mathrm{d}x) > 0.4$.

2.3 Particle Identification.

The mass, M, associated with each charged particle track is deduced from the track momentum, p, and the most probable specific energy loss, $\mathrm{d}E/\mathrm{d}x_0$, which is determined using a Bayesian log-likelihood method [13, 14]. The value of $\mathrm{d}E/\mathrm{d}x_0$ is chosen for each track such that the likelihood function

$$\log L = \sum_i^N \log P(\mathrm{d}E/\mathrm{d}x_i | \mathrm{d}E/\mathrm{d}x_0) \tag{2}$$

is maximised. Here, $P(\mathrm{d}E/\mathrm{d}x_i|\mathrm{d}E/\mathrm{d}x_0)$ is the probability that the i^{th} measured value of $\mathrm{d}E/\mathrm{d}x$ results from a particle with most probable specific energy loss $\mathrm{d}E/\mathrm{d}x_0$ which is treated as a variable in equation 2. This probability is computed from a parameterisation of the Landau distribution. The ratio p/M is then obtained in an iterative way from $\mathrm{d}E/\mathrm{d}x_0$, assuming that the particle is singly charged, using a parameterisation of the Bethe-Bloch formula for the restricted energy loss [15] which includes corrections for apparatus effects. The value of M is then calculated using the measured track momentum. The maximum measurable mass using this technique is beyond the limit set by the centre of mass energy.

Figure 1 (upper plot) shows the specific energy loss for positively charged tracks, determined in this way, plotted against the track momenta. Clear bands can be seen corresponding to pions, kaons, protons, deuterons and tritons. The lower plot shows the spectrum of masses assigned to the tracks using the procedure described above. The smooth curves show parabolic fits to the $\log_{10} M$ distributions (i.e. Gaussians) in each of the different mass peaks. Some deviations from Gaussian behaviour in the tails of the distributions are observed. The resolution is $\delta M/M \sim 7\%$ as determined from the widths of the Gaussian fits. The log-likelihood method adopted here is found to have better mass resolution and leads to a more Gaussian-like distribution than the method used previously by H1 [16]. The particle type for each track is identified as the mass of the closest known particle.

2.4 Background Determination

The distributions of the z vertex coordinate and the distance of closest approach (DCA) of the tracks to the beam line in the transverse plane are used to distinguish the tracks produced in photoproduction from those produced by interactions of the beams with residual gas in the beam pipe, termed beam-gas interactions, or from the secondary interactions of photoproduced

[2] Throughout the paper $\mathrm{d}E/\mathrm{d}x$ is given as the ratio of the specific energy loss of the track to that of a MIP.

particles in the material of the beam pipe or the detector, termed material background. The beam-gas backgrounds are labelled pG for proton-gas and eG for electron-gas interactions.

Figure 2 shows the DCA distributions. Tracks from interactions of the beam particles contribute to the peaks at zero, whereas the material background gives rise to the observed smooth background distributions. The material background for positive tracks results mainly from secondary interactions with the material of the beam pipe or the other material before the CJC sensitive region. This can be seen in the upper plots of figure 2 where it leads to an approximately flat background with small peaks at DCA ~ 4 cm. For negative tracks, the material background is much smaller (see figure 2 lower plots). It arises mainly from protons and deuterons which are back-scattered from the calorimeters into the CJC. These albedo particles, which lie outside the main peak in figure 2, are delayed due to their extra distance of travel by times of about 6 ns relative to the arrival time of tracks coming directly from the photoproduction interaction vertex, as measured in the CJC. The selection of negative particles with masses greater than the proton mass is supplemented by the requirement that this delay be less than 4 ns, which is observed to reduce such backgrounds by about a factor of two.

The number of particles corrected for the material background is obtained by subtracting the number in the sidebands of the DCA distribution ($1.5 < |\mathrm{DCA}| < 3.0$ cm), normalised to the width of the selected region around the peak, from the total number of particles in the peak region. This width is chosen to be ± 1.5 cm for p and $\bar{p}$ and ± 0.5 cm for heavier particles for which the DCA resolution is better.

The beam gas background is measured most accurately by dividing the data into four event samples depending on the presence or absence of energy in the forward part of the LAr or in the backward direction in the SpaCal. The event sample with both forward and backward energy (labelled C_{11} and comprising 89.4% of the total), arises dominantly from photoproduction (γp) which produces a roughly uniform distribution of energy in the apparatus for the $W_{\gamma p}$ range of this measurement. The event sample with forward but no backward energy (labelled C_{10} and comprising 8.5% of the total) arises dominantly from pG interactions, since protons interacting in the interaction region with a nearly stationary target produce mainly forward but little significant backward energy. The event sample with backward but no forward energy (labelled C_{01} and comprising 2.0% of the total), is enriched in eG interactions for similar reasons. Only 0.1% of the events have neither forward nor backward calorimetric energy (sample C_{00}).

The data are separated into the γp, pG and eG components in each sample, C_{ik}, by studying the z vertex distributions (see figure 3). The following procedure is adopted for the separation, the results of which are shown in table 1 for the hard selected tracks. First, the number of γp and pG (eG) tracks in the samples C_{10} (C_{01}), for each particle type, is measured by fitting the z vertex distributions to the sum of a Gaussian and a linear background. The integral of the Gaussian is taken to be the number of particles from γp interactions, $N_{10}^{\gamma p}$ ($N_{01}^{\gamma p}$), while the linear background determines the number of pG (eG) tracks, N_{10}^{pG} (N_{01}^{eG}), in the samples. Here the number of eG (pG) events in the C_{10} (C_{01}) sample is neglected. The number of eG particles in the C_{11} sample is also negligible. When the distribution has no visible Gaussian shape (e.g. figure 3d), the value of $N_{ik}^{\gamma p}$ is so low that a measurement is impossible (the dashes in table 1). Second, the number of pG particles in each C_{11} sample, N_{11}^{pG}, is obtained by assuming that the probability that a true pG event has significant backward energy is small. Hence, the probability that a pG event appears in the C_{11} sample is approximately the probability that random noise

above threshold occurs in the SpaCal calorimeter in a pG event and this should be independent of particle type. This probability is measured from the ratio of the numbers of events in the C_{11} and C_{10} samples for pure pG events, i.e. samples which should have little contribution from photoproduction. Deuterons with z vertex $|z| > 20$ cm and $\cos\theta > 0$ are used for this, as is an independent sample of events with two identified protons and no identified anti-proton, which also shows no significant Gaussian shape in the z vertex distribution. The two independent measurements give ratios which agree within errors, confirming the assumption, with a mean of 0.151 ± 0.045. The quantity N_{11}^{pG} is obtained by multiplying N_{10}^{pG} by this ratio. Finally, the number of γp particles in the C_{11} sample, $N_{11}^{\gamma p}$, is obtained by subtracting N_{11}^{pG} from the total for this sample, N_{11}. The separation into components for the C_{00} sample is made using the probabilities (~ 0.02, estimated from the numbers in table 1) that the photoproduced events have zero energy in the forward and backward calorimeters.

2.5 Track Efficiencies

The apparatus is fully sensitive in the range $0.2 < p_T/M < 0.7$ and $|y| < 0.4$. In order to derive cross sections, corrections for track efficiencies (labelled ϵ) must be applied. These are shown in detail for anti-deuterons in table 2 in the measurement intervals of p_T/M. The efficiencies for anti-protons tend to be somewhat larger than those for anti-deuterons, since the soft selection is used and the secondary interaction cross section is smaller. The efficiencies listed in table 2 are defined as follows.

- $\epsilon_{\mathrm{d}E/\mathrm{d}x}$ is the correction for migrations across the limit $\log \mathrm{d}E/\mathrm{d}x > 0.4$. This is assessed by studying the migrations of anti-protons, selected with the looser criterion $\log \mathrm{d}E/\mathrm{d}x > 0.3$.
- ϵ_ϕ is a correction for a region of inefficiency in the CJC which developed during the data taking.
- ϵ_{cut} is a correction for the loss of events outside the mass and DCA windows.
- ϵ_σ represents the corrections for the losses due to interactions in the material of the apparatus. This is extracted from the data using soft selected, identified tracks. The number of such tracks which are observed to interact in the material between CJC1 and CJC2 is extrapolated to account for the material between the interaction point and the CJC1. The corrections agree with estimates from known cross sections.
- ϵ_{hit} represents the track reconstruction efficiency which is determined by measuring the fraction of soft selected deuterons which enter the hard selection sample.
- ϵ_{trig} is the trigger efficiency which is determined by two independent methods for events containing anti-protons. These are assumed to have the same trigger efficiency as anti-deuterons. One method involves Monte Carlo studies and the other method uses comparisons of the number of events from the main trigger with those found by an independent monitor trigger. The two methods give consistent results.
- ϵ_{tag} is the positron tagger acceptance.

- ϵ_{Nch} is the correction for the loss of events due to the requirement that there be five or more tracks in each event. This is deduced by applying the known KNO scaling distribution [17], using a sample of events containing anti-protons which has an observed mean track multiplicity which matches that for events containing anti-deuterons.
- ϵ_{t0} represents the correction for the losses of anti-deuterons outside the defined track timing interval.
- ϵ_{PhSp} is an estimate of the fraction of anti-deuterons lost outside the measurement region defined by the limits of $|\eta| < 1.0$ and $|y| < 0.4$.

The final row of table 2 gives the measured value of the differential cross section

$$\frac{\mathrm{d}\sigma}{\mathrm{d}(\mathrm{p_T/M})} = \frac{N}{\Delta(p_T/M)\mathcal{L}F}. \tag{3}$$

where N is the number of events in each measurement interval, $\Delta(p_T/M)$, corrected for all the efficiencies given in table 2, $\mathcal{L} = 5.53 \pm 0.11$ pb^{-1} is the integrated luminosity and $F = 0.0136$ is the virtual photon flux per incident positron (for the details of the calculation see [18]). The first error quoted for the differential cross sections is statistical while the second is systematic, where the latter arises from the uncertainties in the efficiencies. All cross sections are quoted at the bin centres.

3 Results

3.1 Search for Heavy Particles

The observed particle mass spectra are shown in figure 4. The dashed curves show the material backgrounds deduced from the sideband subtraction method described in section 2.3. The mainly pG sample, C_{10}, contains 6 tracks which have reconstructed masses of more than 3 GeV. They each have specific energy losses which are approximately twice that expected for a MIP. Visual inspection shows that these are overlapping tracks, probably due to relativistic particles which have been merged by the pattern recognition software, since the two tracks become visible at the ends of their trajectories. No such tracks are seen in the dominantly photoproduction sample, C_{11}, which contains many more events. Since they are dominated by background, the C_{10}, C_{01} and C_{00} samples are omitted from the search for heavy particles in photoproduction.

The observed deuterons and tritons (see table 1 and figure 4) are dominantly from the material background and upper limits on their photoproduction cross sections are derived from the observed numbers of events. These upper limits at the 95% confidence level, in the measurement range defined in section 2.5, are deduced to be 6.8 and 1.0 nb, respectively. No negative particles heavier than anti-deuterons and no positive particles heavier than tritons are observed. This allows an upper limit of 0.19 nb at the 95% confidence level to be set on the photoproduction cross section for any such particle type in the same kinematic range. These cross section limits are derived assuming the same efficiencies as those for anti-deuterons given below.

3.2 The Anti-deuteron Cross Section

A clear signal is seen in figure 4, consisting of a total of 45 anti-deuterons with an estimated material background of 1.0 ± 0.5. The inclusive cross sections are measured using the 35 particles in the sensitive range defined in section 2.5 for all samples combined. Only two of the anti-deuterons are not in the C_{11} sample (both in C_{10}). This number is compatible with that expected from the probability that a photoproduction event has small backward energy ($\sim 2\%$).

The total cross section for anti-deuteron production is found to be $2.7 \pm 0.5 \pm 0.2$ nb in the kinematic range defined in section 2.5, by summing all the differential cross sections in the final row of table 2. The ratio of the number of anti-deuterons to anti-protons in the range $|y| < 0.4$ and $0.3 < p_T/M < 0.7$ is measured to be $(5.0 \pm 1.0 \pm 0.5) \cdot 10^{-4}$. The lower limit in p_T/M is higher for the ratio than for the anti-deuteron cross section measurement in order to avoid the uncertainties associated with the large corrections to the anti-proton rates at low momentum.

The inclusive anti-deuteron invariant cross section is given by:

$$\gamma \frac{\mathrm{d}^3\sigma}{\mathrm{d}^3(\mathrm{p/M})} = M^2 E \frac{\mathrm{d}^3\sigma}{\mathrm{d}^3\mathrm{p}} = \frac{1}{2\pi\ (p_T/M)\ \Delta y} \frac{\mathrm{d}\sigma}{\mathrm{d}(\mathrm{p_T/M})} \tag{4}$$

where $\gamma = E/M$, $\mathrm{d}\sigma/\mathrm{d}(\mathrm{p_T/M})$ are the differential cross sections given in the final row of table 2 and $\Delta y = 0.8$ is the rapidity range of the measurement. Figure 5 and table 3 show the measurements of this invariant cross section, normalised to the relevant total cross section, taken to be $165 \pm 11 \mu$b for photoproduction [18], as a function of p_T/M. Figure 5 also shows the measured ratio of the corrected numbers of anti-deuterons to anti-protons versus p_T/M.

3.3 Comparison with Other Measurements

Measurements of the normalised invariant anti-deuteron cross section and the ratio of the anti-deuteron to anti-proton production rates performed by other high energy experiments in the central region are also shown in figure 5. The normalised cross section and ratio measurements obtained in pp collisions [5,6] and the photoproduction results described here are in good agreement, suggesting that the processes whereby anti-deuterons are formed are similar in pp and γp interactions. The data on Au-Au collisions show a ratio which is slightly larger than that in pp collisions and photoproduction. However, the cross section for anti-deuteron production normalised to the total cross section in Au-Au collisions is over two orders of magnitude larger than that in photoproduction or pp collisions, reflecting the more copious production of anti-nucleons in heavy ion collisions.

The coalescence parameter B_2 is derived by rearranging equation 1 to obtain

$$B_2 = \frac{\frac{1}{\sigma}\frac{E_{\bar{d}}\mathrm{d}^3\sigma_{\bar{\mathrm{d}}}}{\mathrm{d}^3\mathrm{P}}}{\left(\frac{1}{\sigma}\frac{E_{\bar{p}}\mathrm{d}^3\sigma_{\bar{\mathrm{p}}}}{\mathrm{d}^3\mathrm{p}}\right)^2} = \frac{M_{\bar{p}}^4}{M_{\bar{d}}^2} \frac{R^2}{\left(\frac{1}{\sigma}\frac{\gamma_{\bar{d}}\mathrm{d}^3\sigma_{\bar{\mathrm{d}}}}{\mathrm{d}^3(\mathrm{P/M_{\bar{d}}})}\right)}. \tag{5}$$

Here, $M_{\bar{p}}$ and $M_{\bar{d}}$ are the masses of the $\bar{p}$ and $\bar{d}$ and σ, $\sigma_{\bar{p}}$ and $\sigma_{\bar{d}}$ are the total interaction cross section and the partial cross sections for $\bar{p}$ and $\bar{d}$ production, respectively, as defined

in equation 1 with $A = 2$ for $\bar{d}$ production. The quantity, R, is the measured ratio of the number of anti-deuterons to anti-protons from direct production in each bin of p_T/M, corrected for anti-protons formed remotely from the source by weak decays. In the coalescence model, only anti-nucleons produced directly from the source can form anti-deuterons. The number of $\bar{p}$ from direct production is taken to be $78 \pm 8\%$ of the number observed. This is estimated using the PYTHIA Monte Carlo [19], the accuracy being determined by the uncertainty in the strangeness suppression factor in this model. Hence, there is an overall theoretical uncertainty of about 20% in the determination of B_2. The weak decay correction is somewhat larger for heavy ion collisions [7] which is thought to be due to enhanced strangeness production [20].

Figure 6 and table 3 show the parameter B_2, computed according to equation 5 from the data presented here. This quantity is calculated for the ISR data in [5, 6], and is presented in figure 6 as a function of p_T/M. The average value in photoproduction is determined from the data presented here to be $B_2 = 0.010 \pm 0.002 \pm 0.001 \pm 0.002$, where the first uncertainty is statistical, the second systematic from the errors in the efficiencies and the third the theoretical error from the weak decay correction. Figure 7 shows the mean value of B_2 in photoproduction, compared with the mean B_2 values obtained from the ISR pp data and the data of a variety of other experiments as a function of centre-of-mass energy. The value of B_2 measured in photoproduction at $W_{\gamma p} = 200$ GeV is similar in magnitude to the values deduced at lower centre-of-mass energies in pp and pA interactions (labelled "elementary" in figure 7). However, this value of B_2 is over an order of magnitude larger than that observed in Au-Au collisions at RHIC at a similar nucleon-nucleon centre-of-mass energy. Comparison of the heavy ion data with the data from more elementary targets shows that this discrepancy grows with centre-of-mass energy (see figure 7). To illustrate the difference between light and heavy colliding particles, the heavy ion data in figure 7 are restricted to very heavy ions. They are also restricted, at centre-of-mass energy below 50 GeV, to measurements of inclusive deuteron and proton production to avoid threshold effects in anti-deuteron production. The Bevelac data, at which energy the A dependence is weak, are the Ne-Au measurements of [21]. The AGS data are the Au-Pt measurements of the E886 experiment [22], the SPS data are the Pb-Pb measurements of NA44 [23] and NA52 [24] and the RHIC data are from the Au-Au measurements of the STAR Collaboration [7]. The "elementary" data are the pA data of [21, 22, 25], the pp data at the ISR [5, 6] and the photoproduction data presented here.

In the coalescence model for heavy ion collisions, the parameter B_2, varies inversely with both the volume of the fireball at thermal freeze-out and the absolute rate of anti-nucleon production when both the spatial and momentum dependence are included in the model [2]. The $\bar{d}$ to $\bar{p}$ ratio is observed in pp and γp collisions to be close to that in Au-Au collisions, yet there is a much larger anti-nucleon production rate, and a smaller value of B_2 in Au-Au collisions. These facts can be reconciled in the coalescence model if the size of the fireball at thermal freeze-out in pp and γp collisions is much smaller than that in Au-Au collisions.

4 Conclusions

A search for heavy charged particles is made in photoproduction at HERA and anti-deuterons are observed at $\langle W_{\gamma p} \rangle = 200\,\text{GeV}$. Upper limits at the 95% confidence level on the production

cross sections for any type of positive particles heavier than tritons or negative particles heavier than anti-deuterons are set at 0.19 nb in the kinematic range $|y| < 0.4$ and $0.2 < p_T/M < 0.7$. The total cross section for anti-deuteron photoproduction is measured to be $2.7 \pm 0.5 \pm 0.2$ nb in the same kinematic range and the ratio of the number of anti-deuterons to anti-protons is measured to be $(5.0 \pm 1.0 \pm 0.5) \cdot 10^{-4}$ in the range $|y| < 0.4$ and $0.3 < p_T/M < 0.7$. The transverse momentum dependence of the normalised invariant cross section for anti-deuteron production is found to be compatible with that measured in central pp interactions at a centre-of-mass energy of 53 GeV. The production rate per event of anti-deuterons in photoproduction is found to be over two orders of magnitude less than that observed in Au-Au collisions at RHIC, although the ratio of anti-deuterons to anti-protons is only slightly smaller. The coalescence model parameter B_2 is extracted in photoproduction and shown to be similar to that deduced from central high energy pp data and lower energy pA data. Averaging over the measurement range of p_T/M, B_2 is measured in photoproduction at $W_{\gamma p} = 200$ GeV to be $0.010 \pm 0.002(\text{stat.}) \pm 0.001(\text{sys.}) \pm 0.002(\text{theory})$ GeV^2. This value is much larger than that observed in Au-Au collisions at RHIC at a similar nucleon-nucleon centre-of-mass energy. This difference between heavy ion and elementary particle collisions is reduced as the centre-of-mass energy decreases. These observations can be understood within the framework of the coalescence model if the interaction volume at thermal freeze-out in γp and pp collisions is much smaller than that in Au-Au collisions at a centre-of-mass energy of 200 GeV.

Acknowledgments

We are grateful to the HERA machine group whose outstanding efforts have made this experiment possible. We thank the engineers and technicians for their work in constructing and now maintaining the H1 detector, our funding agencies for financial support, the DESY technical staff for continual assistance and the DESY directorate for support and for the hospitality which they extend to the non-DESY members of the collaboration.

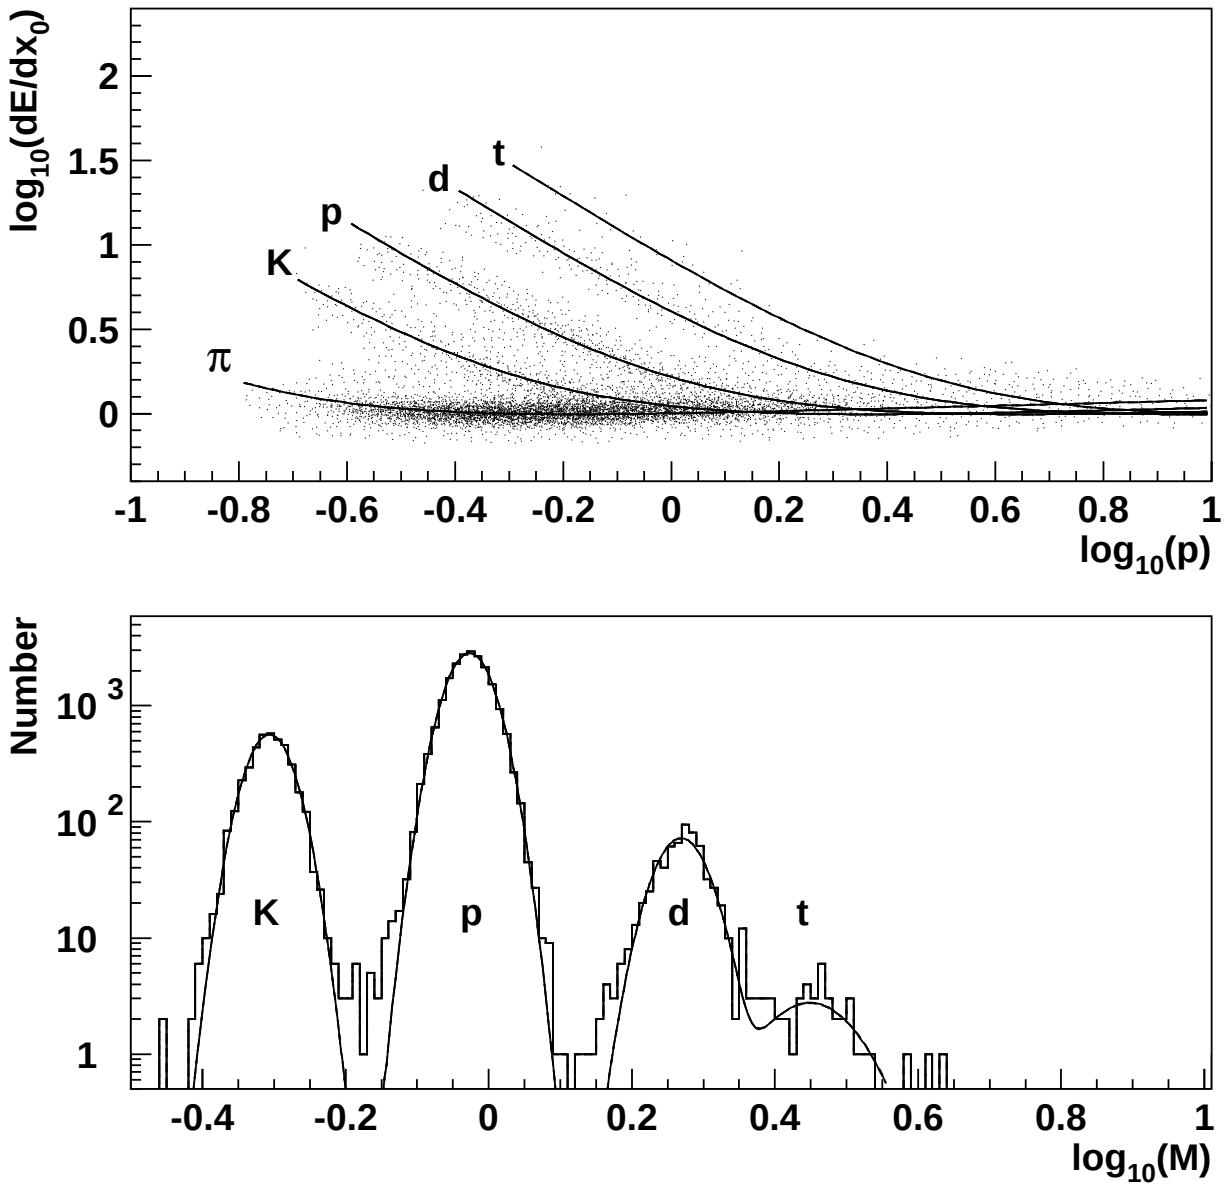

Figure 1: Upper plot - the observed specific ionisation energy loss, $\mathrm{d}E/\mathrm{d}x$, (normalised to that from a MIP), obtained from the log-likelihood method, versus track momentum (in GeV) for a sample of positively charged tracks from the hard selection (before application of the specific energy loss cut, see text). The smooth curves show the expected mean specific energy loss for the different particle species. Lower plot - the spectrum of masses (in GeV) for $\log_{10}\mathrm{d}E/\mathrm{d}x > 0.4$, deduced as described in the text. The smooth curves represent Gaussian fits to each peak.

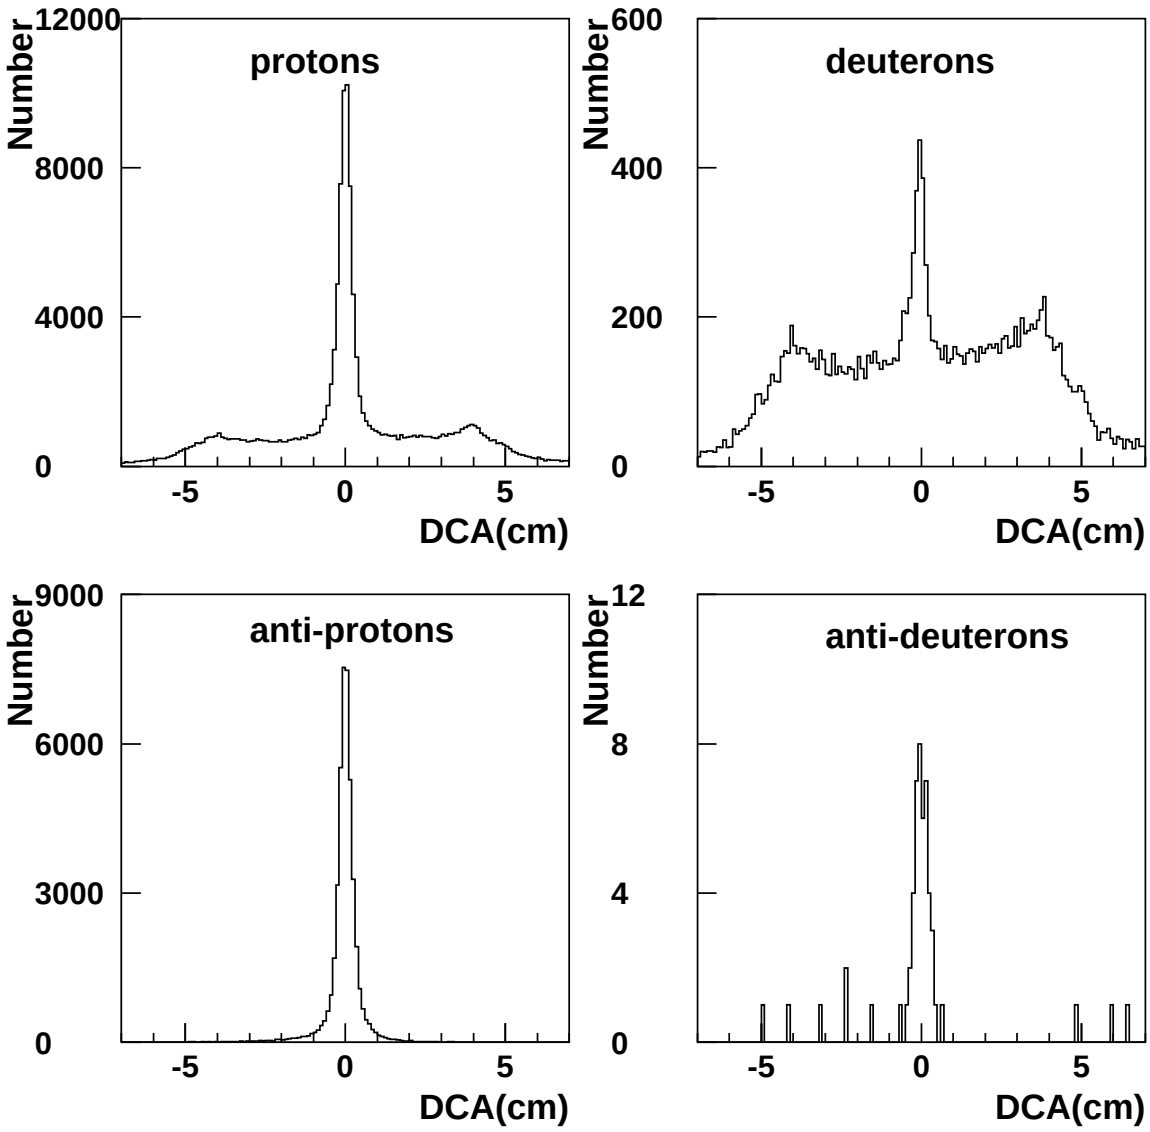

Figure 2: The distribution of the distance of closest approach (DCA) of the track to the event vertex in the plane transverse to the beam direction for p, d, $\bar{p}$ and $\bar{d}$ candidates with momenta larger than $0.5\,\mathrm{GeV}$ from the hard selection and before any track timing cuts. The peak at zero from beam induced events sits on the material background which is much smaller for $\bar{p}$, $\bar{d}$ than for p, d.

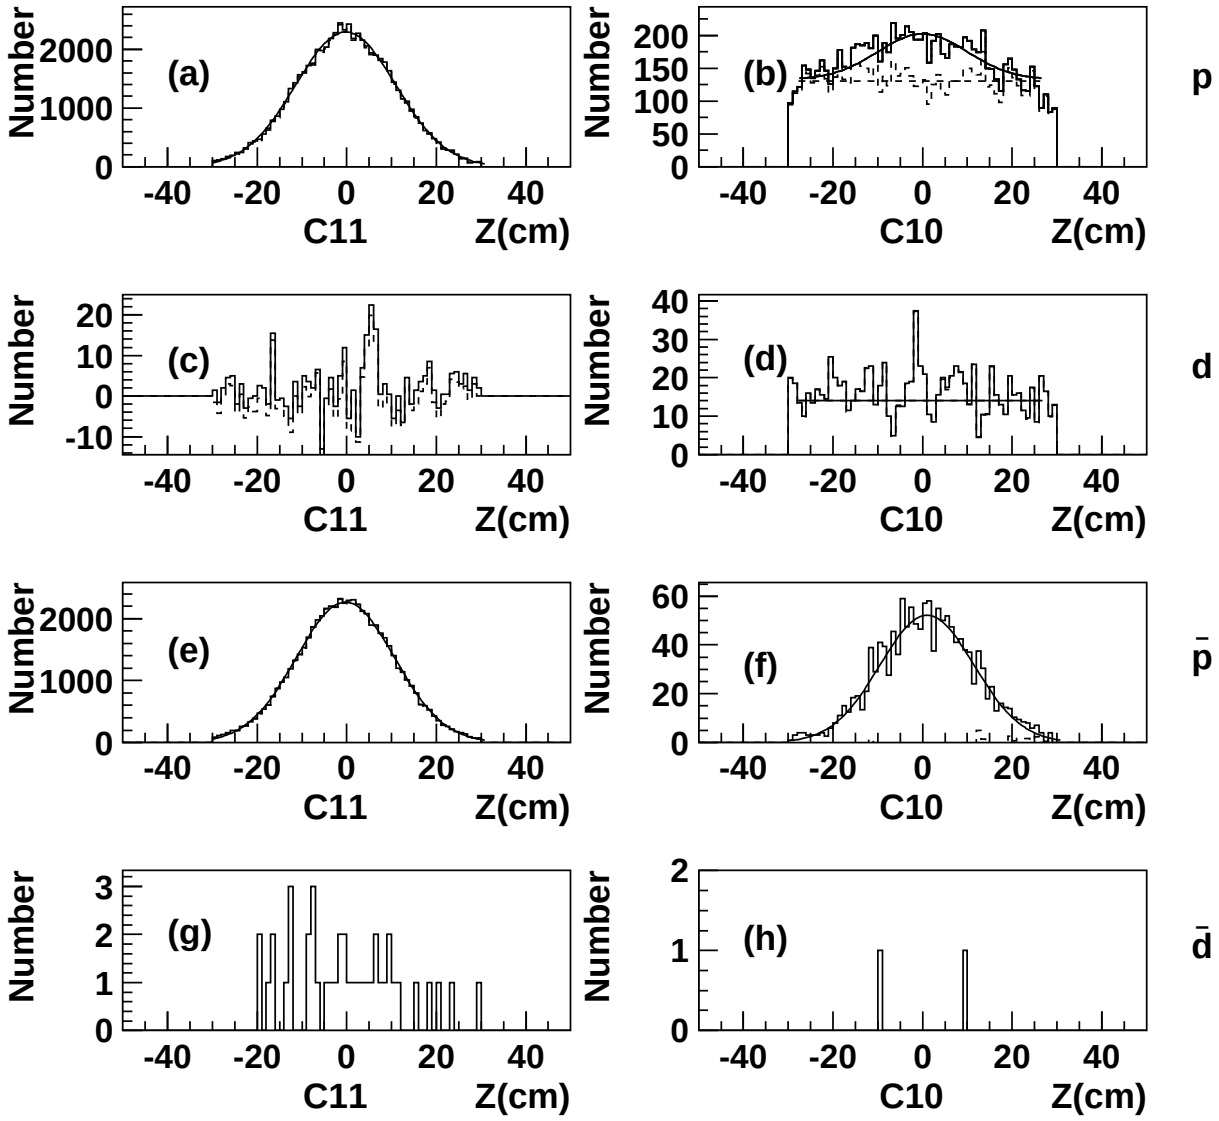

Figure 3: The z vertex distributions for identified protons (a,b), deuterons (c,d), anti-protons (e,f) and anti-deuterons (g,h) in the hard selected samples after correction for the material backgrounds. The C_{11} samples (figures a,c,e,g) are dominated by photoproduction events and the C_{10} sample (figures b,d,f) are dominated by pG events. The solid curves (figures a,b,c,d) show the fits of a Gaussian distribution (expected from photoproduction) and a linear background (expected from pG interactions). The lack of background and the relatively small number of events in (f) show that there is little $\bar{p}$ production in pG events. The number of $\bar{d}$ events in (h) is compatible with that expected from the γp contamination of C_{10} sample. The lack of background in (a) and (e) shows that there are few pG events in the C_{11} sample. The dashed histograms represent the background after subtraction of the fitted (b) or calculated (c,f) Gaussians.

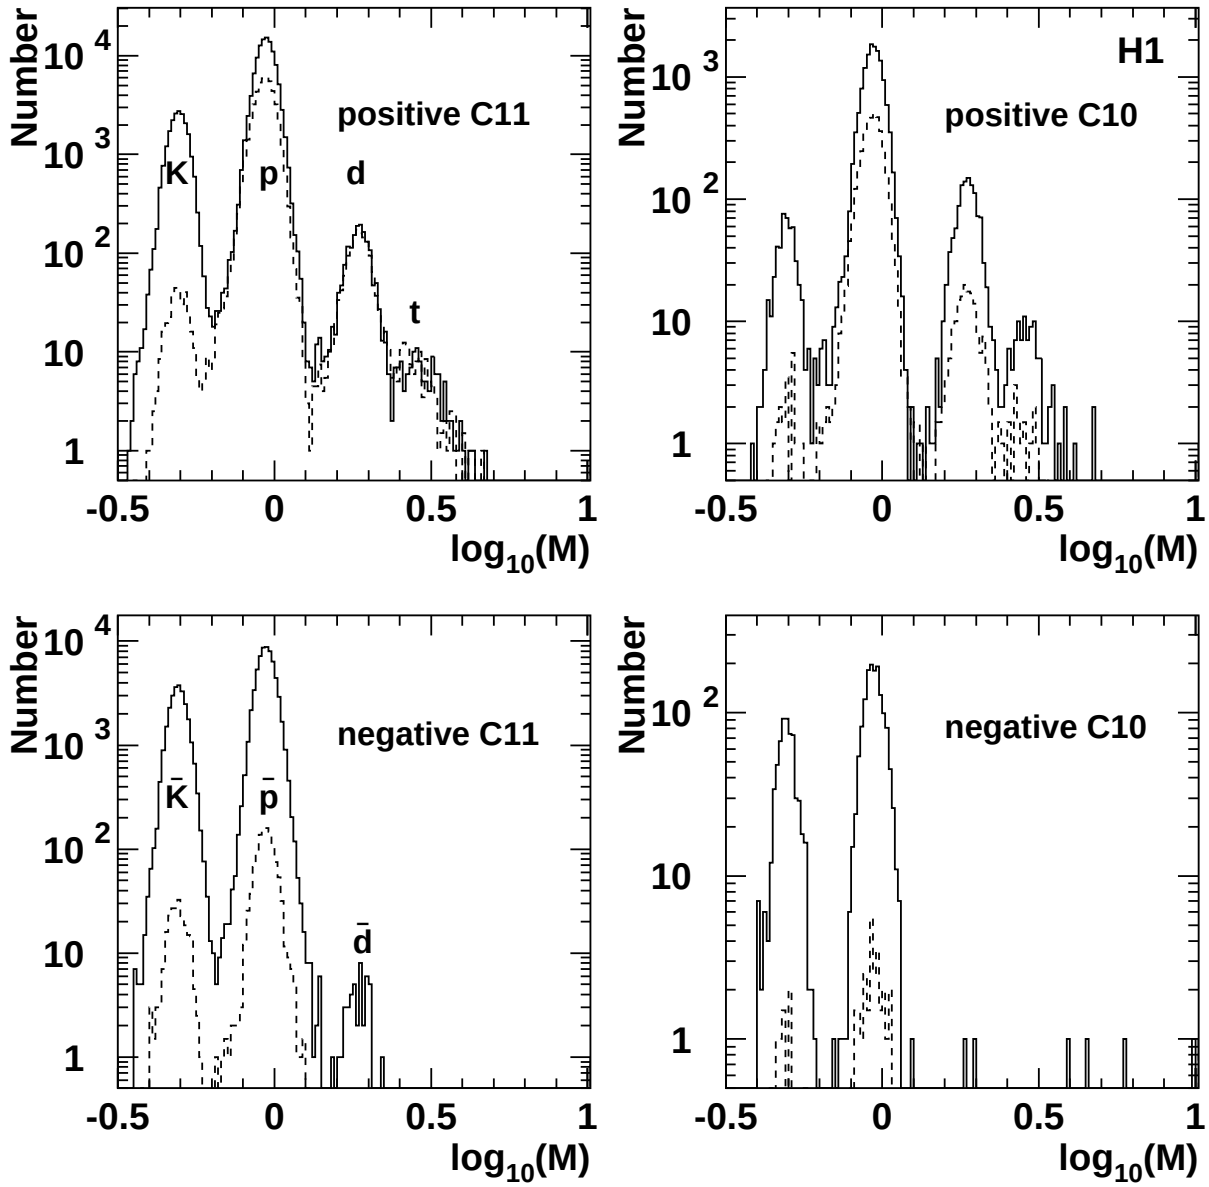

Figure 4: The mass spectra (with M in GeV) for positive and negative particles in the hard selected sample for the mainly photoproduction (C_{11}) and mainly pG (C_{10}) samples. The dashed lines show the material background deduced from the sideband subtraction method.

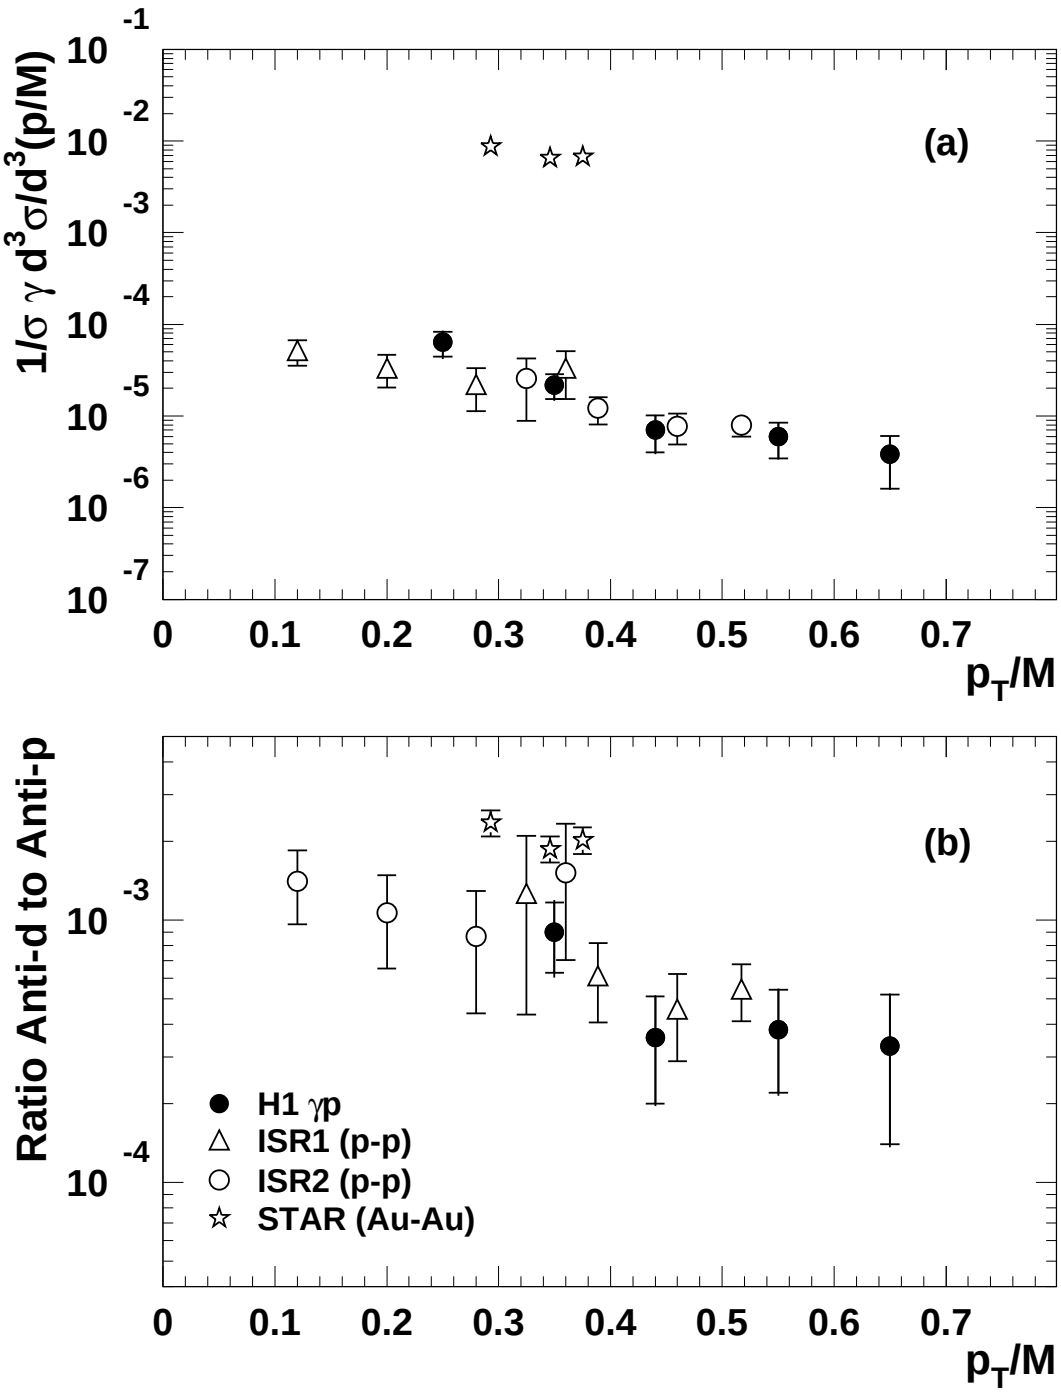

Figure 5: a) The measured invariant cross section (normalised to the relevant total cross section) for inclusive $\bar{d}$ production, compared with the pp and Au-Au data. b) The measured $\bar{d}$ to $\bar{p}$ production ratio as a function of p_T/M (solid points) compared with pp data from the ISR at $\sqrt{s} = 53\,\text{GeV}$ in the central region [5, 6] and RHIC data on Au-Au collisions [7]. The inner error bars on the H1 data indicate the statistical and the outer the total uncertainties.

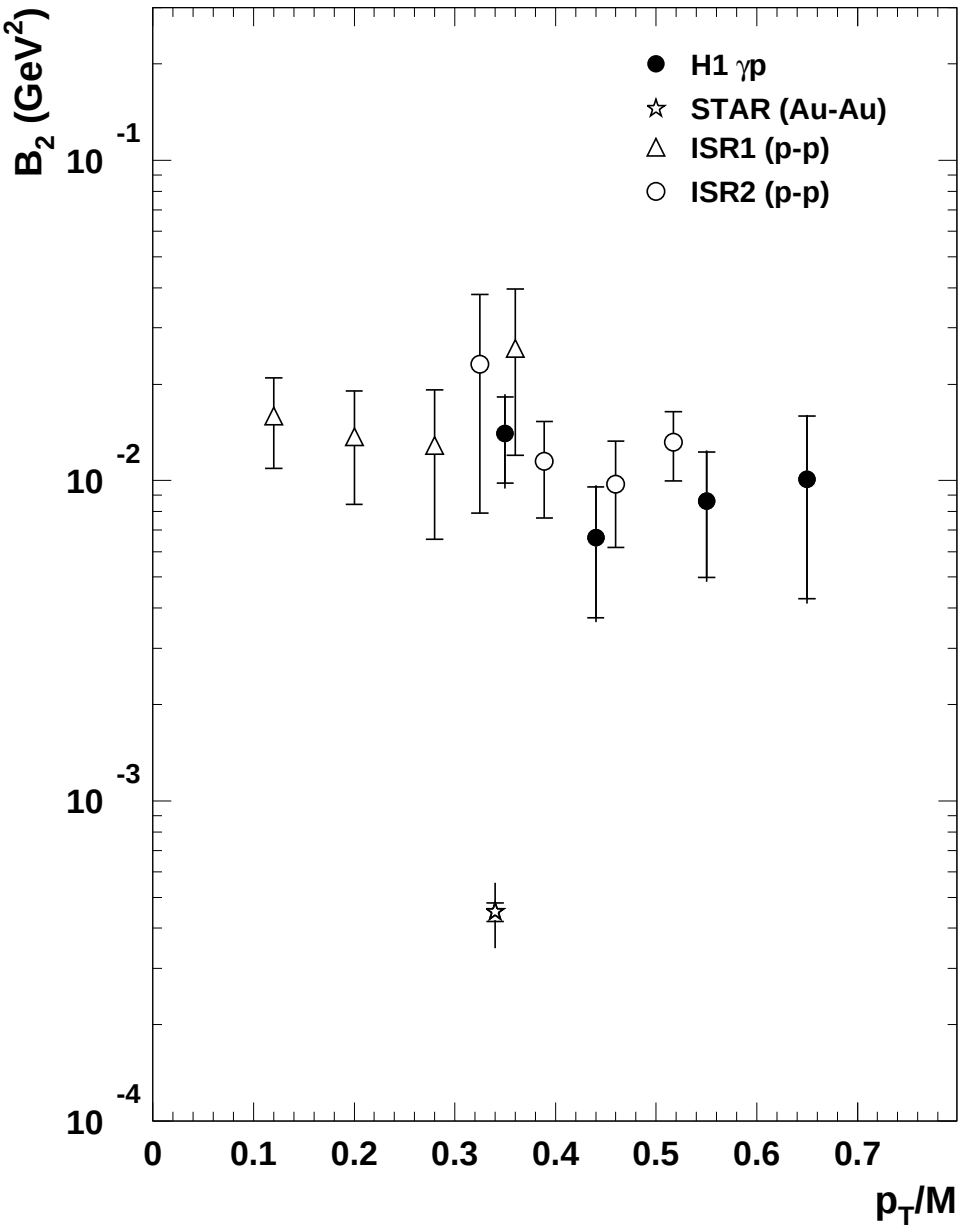

Figure 6: The p_T/M dependence of the parameter B_2 for γp (this experiment), pp [5, 6] and Au-Au interactions [7]. The values of B_2 for the pp data are deduced from the measured cross sections [5, 6]. There is a theoretical uncertainty of about 20% (not shown) in the determination of B_2 for the photoproduction and pp data, which arises from the calculation of the fraction of anti-protons produced directly (see text). The inner error bars on the H1 data indicate the statistical and the outer the total uncertainties.

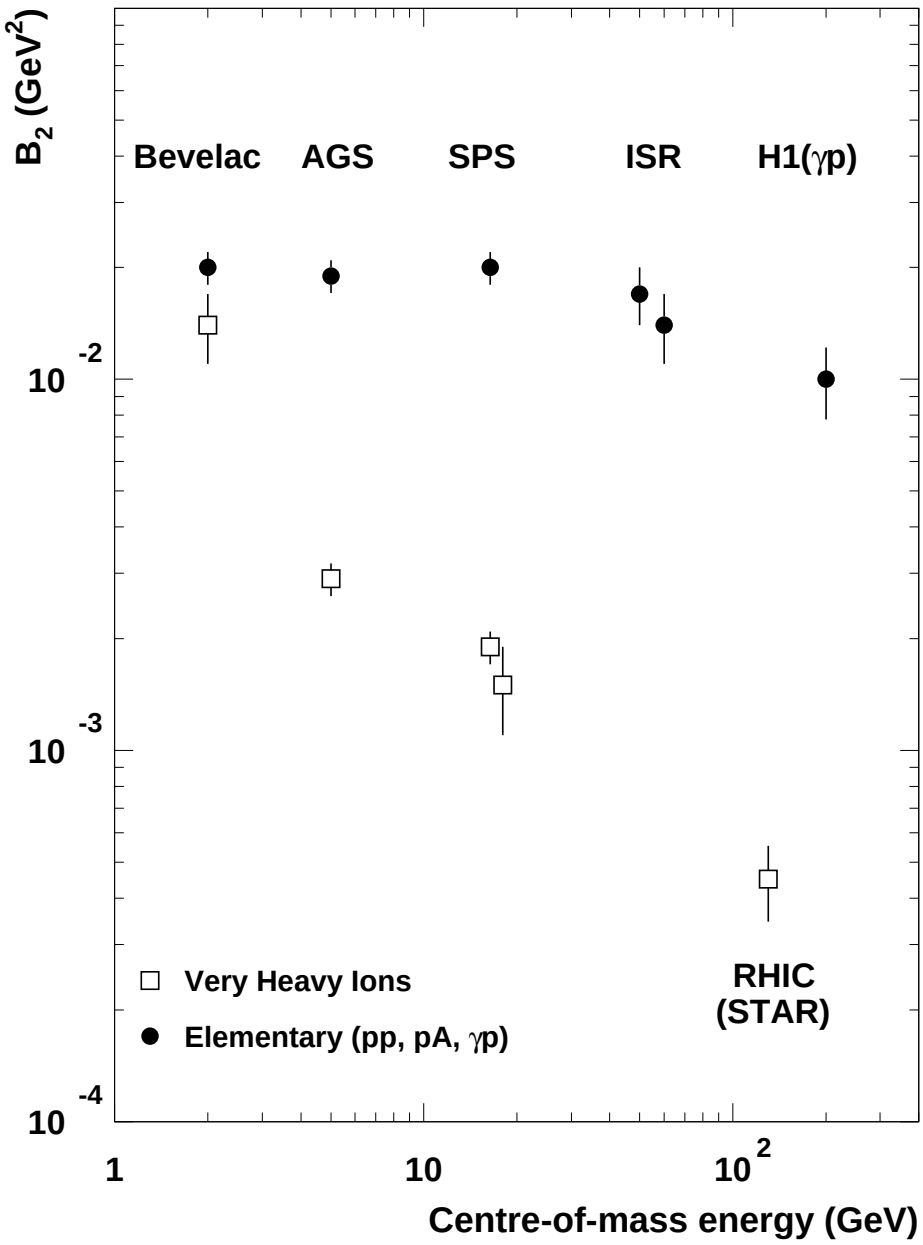

Figure 7: The dependence of B_2 on centre-of-mass energy for very heavy ion collisions (open squares) and interactions of more elementary particles (closed circles). The heavy ion data are the Ne-Au data at the Bevelac [21], the E886 Au-Pt data at the AGS [22], the Pb-Pb data of NA44 [23] and NA52 [24] at the SPS and the Au-Au data of STAR [7] at RHIC. The "elementary" data are the pA data of [21, 22, 25], the pp data at the ISR [5, 6] and the photoproduction data presented here. In the latter the error bar represents the total uncertainty i.e. the sum in quadrature of the systematic and statistical uncertainties.

Table 1: The numbers ($N_{ik}^{\gamma p,pG,eG}$) of photoproduction (γp) and beam gas (pG, eG) hard selected tracks ($\log_{10} \mathrm{d}E/\mathrm{d}x > 0.4$) in the four event samples (see text) for the different particle types. The right hand column gives the observed total number of identified tracks in each category after subtraction of the material background. The quoted errors are the statistical uncertainties.

$\frac{d\sigma}{dp_T/M}(nb)$	$13.1 \pm 3.9 \pm 2.2$	$6.6 \pm 2.0 \pm 0.8$	$2.7 \pm 1.1 \pm 0.3$	$2.7 \pm 1.1 \pm 0.3$	$2.1 \pm 1.2 \pm 0.2$

Table 3: The measured values of the invariant $\bar{d}$ production cross sections, $\bar{d}$ to $\bar{p}$ ratios and coalescence parameter, B_2. The first error is the statistical and the second error the systematic uncertainty.

p_T/M	$\gamma\frac{d^3\sigma_{\bar{d}}}{d^3(p/M_{\bar{d}})}$ (nb)	$R_{meas} = \frac{N_{\bar{d}}}{N_{\bar{p}}} \cdot 10^4$ measured value	$R_{corr} \cdot 10^4$ weak decay corrected	$B_2(\mathrm{GeV}^2)$
