Radiation damage of CsI (T1) crystals in a long term exposure at PETRA

Susanne Schlögl, Hartwig Spitzer and Kay Wittenburg II. Institut für Experimentalphysik Universität Hamburg, FRG

<u>Abstract</u> We have tested the radiation resistance of two 10 cm long CSI (T1) crystals in the radiation environment of the PETRA e^+e^- storage ring. The crystals were exposed for 38 days to an average dose of 50 rad and 20 rad, respectively. The exposure lead to a continuous decrease of pulse height with a final reduction of 13 ± 1 % (crystal 1 with photodiode readout at 50 rad) and 19.5 ± 2 % (crystal 2 with photomultiplier readout at 20 rad). Most of the damage occurred in the first days of exposure. After the end of the exposure we observed a partial recovery of few percent.

1. Introduction

Recently CsI (T1) has been proposed as a scintillator material for high resolution electromagnetic calorimeters 1 - 6). As an example the CLEO upgrade project foresees the use of CsI at the CESR e⁺e⁻ storage ring 5). In many respects CsI is equivalent or superior to BGO. In particular the high light yield with an emission maximum at 550 nm matches well with silicon photodiode readout. One of the properties which might limit the use of CsI at storage rings is its sensitivity to background radiation. Typical radiation levels to be expected are 30 - 100 rad/month at a radial distance of 25 cm from the interaction point of the DORIS ring.

Previous work on the radiation resistance of long CsI crystals concentrated on short term exposures to the radiation of Co^{60} and Cs^{137} sources ^{7,8}).

The studies revealed the following picture:

- 1. From exposures of up to 100 rad the pulse height of CsI decreases substantially (up to 25 %).
- At low doses the initial damage grows linearly with dose, whereas at higher doses (above 100 rad) saturation effects occur. Fig. 1 illustrates the results.
- 3. The radiation damage does not recover spontaneously, however it can be cured by heat treatment $^{4)}$.

The previous measurements were performed using photomultipliers, which had maximum quantum efficiency below 500 nm. From experience with BGO and scintillator we would expect, that the radiation damage is less severe at wavelengths above 500 nm where silicon photodiodes have a good quantum efficiency. Both, the damage recorded with photodiode readout and the cumulative effect of small daily doses over an extended period of time have not yet been reported. We have therefore tested the radiation susceptibility of CsI crystals (1.5x1.5x10 cm³) using photomultiplier and photodiode readout. The crystals were exposed under realistic conditions in a partially shielded position on the beampipe of PETRA for 38 days.

2. Experimental procedure

In the following we first describe the setup for pulse height measurements and subsequently the irradiation procedure.

Fe

The setup is similar to the one described in ref. 8. The two crystals had the following properties (table 1):

Crys- tal	Manufac- turer	Size (mm³)	Delivery date	Cs res. ∆E/E ¹	Uniformity ²
1	BDH, Poole, Dorset, England BH 12 4NN	15x15x100	Oct. 83	7±0.5 %	5.5 %
2	п	15x15x100	Oct. 83	10±0.5 %	8 %

Table 1 Properties of test crystals

The crystals had all sides polished. They were wrapped in white reflective foil (aluminized Mylar sprayed with TiO_2 paint). Crystal 1 was glued with optical glue to a Hamamatsu S1790 silicon photodiode, which had a sensitive area of 1 cm². Using this diode the crystal gave a light yield corresponding to 10 400 photoelectrons/MeV. Crystal 2 was glued to a Hamamatsu R268 photomultiplier which has a spectral response from 300 - 650 nm with a maximum at 420 nm. During handling the crystals were kept under red light. The photodiode on crystal 1 was readout via a charge sensitive preamplifier (Canberra 2003BT), a shaping amplifier and a multichannel analyzer. The readout of the photomultiplier on crystal 2 was the same as in ref. 8. The drift of the multiplier and the readout electronics was monitored by an LED which was glued to the photocathode window.

The irradiation was performed by mounting the crystals in a partially shielded location on the PETRA beampipe next to the CELLO detector. Fig. 2 shows a side view of the detector layout. Two boxes containing the crystals were put on the beampipe about 60 cm away from the mini β -quadrupole (1). The average radial distance of the crystals from the beam was 15 - 25 cm. The beampipe was wrapped between points (n) and (o) by 4 mm of lead. Further radiation protection was provided by an iron wall (f), a lead brick wall (k) (total thickness 5 cm) and a lead glass shower counter (h). Three beam halo absorbers were placed in the beampipe at positions (n), (o) and (p). The boxes themselves were covered by a 1 mm layer of lead.

The scintillation light yield of crystal 1 was measured by positioning an uncollimated 3.6 μ Ci Bi²⁰⁷ γ source mounted 2 cm away from the narrow end face. Crystal 2 was monitored by a 10 μ Ci Cs¹³⁷ γ source mounted 3 cm away from the narrow end face. The crystal temperature was measured by a temperature sensor mounted near each crystal. Fig. 3 shows the temperature variation during the measuring period. The results given below have been corrected assuming a temperature coefficient of -0.3 %/K for CsI ⁹) and of -0.6 % /K for the LED's.

3. Radiation dose and results

The crystals were exposed for a total of 38 days. The radiation dose was measured by thermoluminescent dosimeters (TLD) mounted on the side of the crystal facing the beam and on the opposite side as indicated in the insert of fig. 2. The measured integrated doses are shown in tab. 2.

	Crystal	Readout	Integrated dose						
	1	Photodiode S1790	No. of TLD	6	7	8	9		
			dose (rad)	26.3	37.5	84.4	60.7		
_ <u>, , , , , , , , , , , , , , , , , , , </u>	2	Photomulti- plier R268	No. of TLD	1	2	3	4		
			dose (rad)	15.4	18.7	27.6	16.9		

Table 2 Integrated dose measured by the TLD's shown in the insert of fig. 2

We observe large dose variations of 26 to 84 rad for crystal 1 and 15 - 27 rad for crystal 2. The accuracy of each dose measurement was determined to be 10 % by placing several TLD's at one particular location. We attribute the large variations to inhomogenities in the radiation field resulting from nonuniform distribution of material around the beampipe.

Although we did not measure the day to day dose variations, we expect that the total dose was not received in one or two big accidents but rather in a more continuous way.

² Uniformity of pulse height (ph) given by (max.ph - min.ph)/ max.ph measured over 8 cm of the crystal length.

4

PETRA had typically six successful fillings per day and an average of 12 hours of continuous beam per day. The beam energies were between 22.1 and 23.3 GeV.

In order to illustrate the energy range of the radiation hitting the crystal we show in figs. 4 (a) - (c) three energy spectra measured (a) in a period with no beam, (b) during injection ($E_{beam}=6.9$ GeV) and (c) during a typical luminosity run ($E_{beam}=21.1$ GeV), From fig. 4 we observe the following:

- 1. With beams off the pulse height spectrum of crystal 1 has three peaks resulting from noise (pedestal) and the 570 and 1060 keV lines of the ${\rm Bi}^{207}$ source.
- 2. During injection this structure is still seen superimposed upon a low energy background from the storage ring.
- During a luminosity run the background is the dominant signal, peaking at 250 keV and obscuring the source peaks.

The corresponding spectra from crystal 2 (fig. 5) show the following pattern:

- 1. During injection (fig.5 (a)) two peaks show up. One is from 662 keV photons of the cesium source. The leftmost peak is the 30 keV k- α line of barium atoms in the cesium source which are excited by synchrotron radiation. Although this peak is prominent, 30 keV photons are absorbed in the first few mm of the crystal and will contribute little to the overall radiation damage. The continuum between both peaks is a superposition of inherent machine background radiation and backscattered photons from the cesium source.
- During a luminosity run (fig. 5 (b), (c)) the machine background peaking at 250 keV is the dominating pattern.

Figs. 6 (a) and (b) show the pulse height history of crystal 1 as monitored by the 570 keV and 1060 keV lines of the Bi^{207} source in periods between fillings (no beam). The pulse height is normalized to the average value before the exposure. We observe an abrupt decrease in the first ten days of the exposure which then becomes more gradual. After 38 days the pulse height dropped to 88 ± 1 % and 86 ± 1 % of its initial value for the two lines.

Note that the temperature was stable within 1° until the end of the exposure, so that uncertainties in the correction for the temperature dependence are negligible. The estimated systematic uncertainty is 1 %. After the end of the exposure the crystal was removed from the beam within one hour and monitored for another 15 days. We observe little change in the pulse height.

The data indicate a small continuous recovery by 2 %. Assuming the temperature coefficient given in ref. 3 (+ 0.3 %/degree at 20° C for photodiode readout) the recovery is 4.5 %.

Fig. 7 shows the pulse height history of crystal 2 with photomultiplier readout. Here we observe a similar pattern. The pulse height drops rapidly in the first days of the exposure and then at a much slower rate. After 38 days it reaches 80.5 \pm 2 % of its initial value, a somewhat greater loss than for crystal 1, although the absorbed dose is smaller by a factor 2.5. We conclude that the damage is more severe in the 370 - 470 nm wavelength range monitored by the photomultiplier with good efficiency than in the range above \sim 470 nm.

After removal of the crystal from the beam the corrected pulse height rises within hours by 3 % to 83.5 % \pm 2 %. Assuming the temperature coefficient of ref. 3 (+ 0.6 %/degree for multiplier readout) the rise is 6.5 %. The rise is somewhat larger than that observed in crystal 1 with photodiode readout indicating a slightly different recovery pattern at shorter wavelengths.

4. Summary and discussion

From a 38 day exposure of two CsI (Tl) crystals in a partially shielded position on the PETRA ring we observed the following:

- 1. Irradiation of a 10 cm long crystal with silicon photodiode readout by 50 rad (with substantial dose variation along the crystal) led to a pulse height reduction of 13 \pm 1 %. The pulse height recovered slightly after the end of the exposure by 2 4.5 %.
- 2. Irradiation of a similar crystal with photomultiplier readout by 20 rad led to a pulse height reduction of 19.5 \pm 2 %. The spontaneous recovery was of the order 3 6.5 %.
- Most of the pulse height reduction occurred in the first 10 days of the exposure.

In conclusion, the pulse height reduction seems to depend on the wavelength of the light. It is preferable to use photodiode readout, which samples larger wavelengths with a greater efficiency. We observe that the relative loss of pulse height per absorbed radiation dose is much smaller for crystals which have already been exposed for about 10 days to a few tens of rads than for virgin crystals. In calorimeter applications of CsI at e^+e^- storage rings it will be necessary to monitor the pulse height response regularly in order to cope with the radiation damage.

Acknowledgements

We thank Maren Riebesell for help with the test. The help of Mr. Ebeling with processing of the dosimeters is gratefully acknowledged. This work was supported by the Bundesministerium für Forschung und Technologie, Bonn.
